EXPERIMENTAL OCULAR HISTOPLASMOSIS*

ROBERT DAY, M.D.
Baltimore, Maryland

Human infection with Histoplasma capsulatum was first described by Darling in 1906,[1] but only during the past 10 years has this disease become of general interest and of possible significance in ophthalmology.

Darling's original case was a 27-year-old Negro of the Canal Zone who, on clinical examination, was thought to have miliary tuberculosis. At autopsy, however, there was found a widespread infection of lungs, liver, spleen, blood, and lymph nodes with a small oviform organism about three microns in diameter. Darling believed it to be a parasite related to the Leishmania of kala azar. It was free in the tissues and was also widely phagocytosed by the reticulo-endothelial cells of the affected organs.

In 1934, the nature of this parasite was established.[2] De Monbreun cultivated a fungus from a fatal infection of a 6-month-old Tennessee infant. This occurred in both a yeast and a mycelial form and produced in monkeys a disease similar to the human infection from which it was recovered.

Conant,[3] in 1941,, made a careful study of the fungus which he classified among the moniliaceae of the Fungi imperfecti. The mycelial form has aerial branching septate hyphae containing large and small, round, pyriform, or tuberculate chlamydospores (figs. 1 and 2). On synthetic media the fungus ordinarily assumes the mycelial form, but in infected animals it appears as a thin-walled, oval, yeastlike cell about 2 by 3μ which reproduces by a single bud

---

from the end of its long axis (figs. 1 and 3).

Prior to De Monbreun's work in 1934, only 11 cases of histoplasmosis had been reported. All ended fatally. Since then, more than 80 additional fatal cases have been described. Parsons and Zarafonetis[4] summarized these up to 1945 and described lesions of skin, mucous membrane, nasopharynx, lymph nodes, lungs, liver, spleen, gastrointestinal tract, and blood. Ocular lesions were mentioned only once, as "small white irregular areas, surrounded by hemorrhage, in the ocular fundi, not unlike tubercles." The eyes from this case, reported by Reid and others in 1942, were unfortunately not obtained at autopsy.[5]

Simultaneous with the increased recognition of the fatal form of the disease, there developed a growing suspicion that nonfatal cases existed, perhaps on a large scale. Pulmonary calcifications, resembling those of tuberculosis, in negative reactors to tuberculin have long been known.[6-11] Various hypotheses have been offered to explain them, such as pneumonoconiosis, skin anergy in tuberculosis, and mycotic infection.

In 1938[6] the study of this problem received impetus from the observation that routine X-ray examination showed an unusually high number of such pulmonary calcifications in persons from Tennessee and neighboring states. In 1943, Dr. C. E. Smith of Stanford University suggested to Dr. Amos Christie of Vanderbilt University that mild histoplasma infections might explain this peculiar abundance of pulmonary lesions in persons insensitive to tuberculin.
Fig. 1 (Day). Histoplasma capsulatum. (1) represents the yeast form of the fungus.
(2 to 22) represent the hyphae and chlamydospores of the mycelial form of the fungus
in various stages of development. (N. F. Conant, 1941.)

In 1945, Christie[12] reported the results of a study of Tennessee school children tested with tuberculin and with histoplasmin, an antigen obtained from a broth culture of the mycelial form of the fungus. Seventy-nine of 181 children had pulmonary lesions demonstrable by X ray, resembling those of tuberculosis. Of these 79 only 3 were sensitive to tuberculin alone; 48 were sensitive to histoplasmin alone. Comparable results were

thereafter obtained in other similar studies of both adults and children.[13-18] In spite of the uncertain specificity of the histoplasmin skin test,[19-20] these reports strengthened the possibility that there exists, particularly in all cases. All had positive histoplasma complement fixation reactions;[22] 4 gave positive skin reactions to histoplasmin and negative reactions to tuberculin (the 5th case reacted to both antigens). Four of these patients
Fig. 2 (Day). Histoplasma capsulatum, mycelial form. (N. F. Conant, 1941.) (1) Gross appearance on Saboraud's agar. (2 to 4) Microscopic appearance of spores and aerial hyphae.

the central and east-central United States, a subclinical form of fungus disease which produces lesions not unlike those of tuberculosis.

The concept of a nonfatal form of histoplasmosis is further supported by the report in March, 1948, of Bunnell and Furcolow[21] from Kansas City. These observers reported nonfatal infections with Histoplasma capsulatum, 2 in adults and 3 in children. The organism was recovered from also had pulmonary calcifications demonstrable by X ray.

A fatal fungus disease, histoplasmosis, is now definitely recognized. This disease produces in many organs granulomatous lesions resembling those of tuberculosis. A milder form of the disease is also recognized, and widespread subclinical or arrested infections are suspected. It seems possible that some cases of granulomatous uveitis may be due to ocular infection with Histoplasma cap-
Fig. 3 (Day). Histoplasma capsulatum, yeast form. (2) Gross appearance. (1, 3, and 4) Yeast cells, (5) Transitional form. (W. A. De Monbreun, 1934.)

sulatum. To test this hypothesis preliminary clinical and experimental studies have been made.

A. CLINICAL STUDIES

One hundred eighteen unselected cases on the public wards of the Wilmer Institute were tested with histoplasmin by intra-cutaneous injection with 0.1 cc. of histoplasmin (H-15 or H-3), diluted 1:100 and 1:1000. Positive reactions were those in which induration and erythema measured more than 5 mm. in diameter 48 hours after injection. No selection was made either by

race, age, or sex. (The H-15 was obtained through the courtesy of Dr. Arden Howell, and the H-3, through the courtesy of Dr. Chester Emmons, both of the United States Public Health Service.)

Twenty-one of the 118 cases had either active or inactive uveitis. Of the 97 patients without uveitis 29, or 30 percent, gave cutaneous reactions to histoplasmin. This figure compares closely with the 31.9 percent found

these 4, 2 had a single attack of choroiditis, 1 had recurrent choroiditis, and 1 had a single attack of acute granulomatous anterior uveitis. The remaining 10 patients had other positive clinical findings which indicated other possible causes of uveitis.

B. Experimental studies

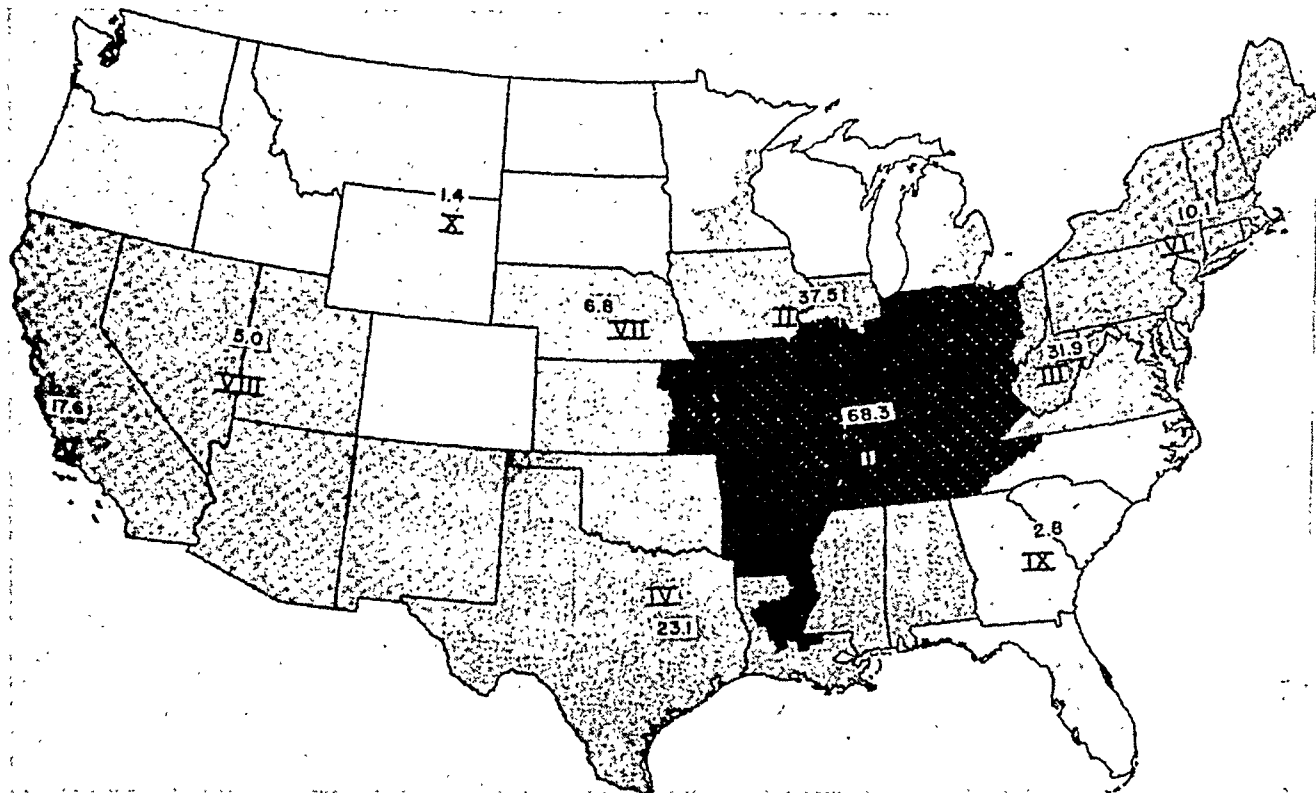
In order to study histoplasma infections of the eye, both uninfected and previously


Fig. 4 (Day). Histoplasmin sensitivity among student nurses classified by state of lifetime residence. (C. E. Palmer, 1946.)

by Palmer, in 1946, for student nurses of the Maryland area[23] (fig. 4). Fourteen, or 67 percent, of the 21 cases of uveitis had positive skin reactions as compared with 30 percent for the group without uveitis. This difference is unlikely to occur by chance. Four of these 14 histoplasmin reactors did not react to intracutaneous injection with 1 mg. of old tuberculin or with 0.1 cc. brucellergin; they had negative serologic tests for syphilis, were apparently free of foci of infection, and had normal serum albumin/globulin ratios. They did have pulmonary calcifications and were sensitive to histoplasmin. Of

infected rabbits were inoculated with the mycelial form of the fungus. The clinical course and histologic picture were then studied.

1. The ocular reaction in normal rabbits

Seventeen eyes in 15 previously uninfected young adult albino rabbits were injected with living spores via the anterior chamber. The technique of the injection was as follows:

The fungus was scraped from a two weeks' growth on Saboraud's agar at room

temperature, was then suspended in saline, and ground to a smooth suspension with a sterile mortar and pestle. A spore count was then made with a blood-counting chamber. The suspensions contained from 125,000 to 3,000,000 spores per cc. Using a sterile syringe and hypodermic needle, 0.05 to 0.2 cc. of aqueous was removed from the anterior chamber. An equivalent amount of the suspension was then injected by the same needle without removing it from the

reflected light, could often be seen on trans-illumination as minute opacities seeded throughout the iris. These scattered nodules grew larger, the iris vessels became more dilated, and, within a week or two, a diffuse exudative nodular iritis occurred (figs. 5, 6, and 7). Within another 1 to 2 weeks, the angle in most cases became blocked and secondary glaucoma developed with vascularization and edema of the cornea (fig. 8). After 2 to 4 weeks of severe inflammation

Fig. 5 (Day). Rabbit D-10, L.E. Two weeks after infection with H. capsulatum.

Fig. 6 (Day). Rabbit D-22, L.E. Three weeks after infection with H. capsulatum.

anterior chamber. From 10,000 to 300,000 spores were thus introduced.

Ten eyes in 10 rabbits developed nodular iritis. An inflammatory reaction followed within 24 hours after infection. The iris and pericorneal vessels became dilated and an exudate appeared in the pupillary space, over the anterior iris, and frequently on the posterior cornea. This immediate reaction either subsided within a week, leaving the eye quiescent for 2 or 3 weeks, or, in most cases, persisted without appreciable change for 1 or 2 weeks.

In those eyes in which the initial reaction subsided, iris nodules appeared 1 to 4 weeks after infection. These were single or multiple, but, even when apparently solitary by

and progressive buphthalmos, the signs of inflammation began to subside (fig. 9). The total period of acute inflammation was thus 4 to 6 weeks. At this interval after infection, the skin test became positive. Two to 3 months after infection, the eyes were quiescent with nodular scars in the irides and leukomatous corneas.

The eyes in which the initial inflammation failed to subside developed a severe nodular iritis 1 to 2 weeks after infection (fig. 10). This led to a buphthalmos and corneal scarring indistinguishable from that of the less fulminating form of iritis described in the last paragraph.

Five eyes in 5 normal rabbits developed buphthalmos within the first week after in-

Fig. 7 (Day). Rabbit D-6, L.E., Six weeks after infection with H. capsulatum.
Fig. 8 (Day). Rabbit D-14, L.E. Six weeks after infection with H. capsulatum.

fection, thus making it impossible to follow the course of the disease. However, in these rabbits the skin test to histoplasmin became positive, and yeast cells were found in 3 eyes on microscopic examination. The corneal scarring and buphthalmos were indistinquishable from that already described.

Two of the above rabbits were infected simultaneously in both eyes; one eye was removed from each rabbit a week after in-

fection, before the development of a nodular iritis.

2. Development of cutaneous sensitivity

All rabbits were initially insensitive to 0.1 cc. of a 1:10 dilution of H-3 histoplasmin given intradermally. The animals were then given periodic intracutaneous injections with 0.1 cc. H-3 histoplasmin (1:10 and 1:100).

Fig. 9 (Day). Rabbit D-10, L.E. Ten weeks after infection with H. capsulatum.
Fig. 10 (Day). Rabbit D-11, L.E., Two and one-half weeks after infection with H. Capsulatum.

A few rabbits were skin sensitive to H-3 (1:10) 2 to 4 weeks after infection. The majority became skin sensitive in 4 to 6 weeks. By the end of the 6th week after infection all rabbits but one, regardless of the route of infection, were skin sensitive to 0.1 cc. of 1:10 and 1:100 H-3. The organism was recovered by culture, however, from the insensitive rabbit 6 months after infection.

3. THE OCULAR REACTION IN PREVIOUSLY INFECTED RABBITS

In order to determine whether previous infection altered the clinical course of subsequent reinfection, 8 of the 15 rabbits used in the initial experiment were reinfected in the anterior chamber of the other eye from 2 to 14 weeks after the original infection and after enucleation of the previously infected eye. None of the previously uninfected eyes showed clinical signs of disease at the time of reinfection.

Five eyes were inoculated in 3 rabbits given previous extraocular infection. One of these received an intravenous injection of 1,000,000 spores 1 month before the ocular injection. The other 2 rabbits received 500,000 spores each by retrobulbar inoculation 1 month and 2 months respectively before the ocular injection. None of the eyes of these rabbits showed signs of clinical infection at the time of reinfection.

Altogether 13 eyes were inoculated in 11 previously infected rabbits. Seven of the 13 eyes were in 5 rabbits which had been inoculated 2 to 4 weeks previously, either systemically or in the anterior chamber. Three of these eyes developed nodular iritis, 2 developed buphthalmos and simultaneous iritis, 1 had a bacterial panophthalmitis, and 1 eye was enucleated a few days after infection so that its clinical course was not followed. The disease process in these eyes closely resembled that in the primary infections already described.

The remaining 6 eyes, in 6 rabbits, originally infected 6 to 14 weeks previously,

had an initial inflammatory reaction after reinfection but failed to develop iritis.

Under the conditions of this experiment it appears that some immunity is conferred by ocular or systemic infection and that this immunity develops its effect in 4 to 6 weeks.

4. THE OCULAR REACTION AFTER INTRAVENOUS INJECTION

Five rabbits were given intravenous injections of the fungus. One case of spontaneous ocular infection occurred. This rabbit received an initial injection via an ear vein of 1,000,000 spores. Two weeks later he received 1,500,000 spores intravenously. Four weeks after the original injection he was skin sensitive to 0.1 cc. 1:100 H-3. Three months after the original injection, a third intravenous injection of 1,125,000 spores was given, and 3 weeks later, a fourth injection of 1,500,000 spores.

One week after the last injection, the pupil of the left eye was peaked from the 1- to 5-o'clock positions. There was a bloody exudate in the lower anterior chamber. The aqueous was clouded with a fibrinous exudate. A good red reflex was obtained but no fundus details could be made out. During the next 2 weeks the eye whitened, but the pupil remained peaked at the 3-o'clock position and there appeared to be a mass behind the iris at that point. There were many coarse intravitreous opacities.

The eye was enucleated. On histologic examination the positive findings were a small collection of round cells in the ciliary body, a few round cells in the vitreous, and one giant cell in the ciliary body which contained no yeast cells.

5. THE OCULAR REACTION AFTER INTRAVITREOUS AND RETROBULBAR INJECTION

Localized vitreous abscesses developed in 4 eyes of 2 rabbits following intravitreous inoculation. These progressed for 1 to 2 weeks and then slowly regressed, leaving heavy localized opacities.

No clinical change was observed in the
Fig. 11 (Day). Rabbit D-1, L.E. One week after infection with H. capsulatum. Exudate in anterior chamber, round cells, a few polys, and mycelial debris. (Left ×35; right ×600.)

eyes of 2 rabbits following retrobulbar injection.

6. THE OCULAR REACTION AFTER INOCULATION WITH HEAT-KILLED SPORES

Three eyes in 3 rabbits were inoculated in the anterior chamber with heat-killed spores. These eyes, except for an initial inflammatory reaction which subsided within a week, did not develop iritis.

7. SUMMARY OF OCULAR REACTIONS

To recapitulate, normal rabbits when injected via the anterior chamber with a saline suspension of the mycelial form of Histoplasma capsulatum developed a nodular iritis which led to secondary glaucoma, buphthalmos, and the loss of the eye.

The interval between infection and the appearance of the nodular iritis varied with the size of the infecting dose. Animals in-
Fig. 12 (Day). Rabbit D-1, R.E. One week. Massive exudate in anterior chamber, polys, round cells, fibrin. Note two spores near center of high-power photomicrograph (right ×600). (Left ×35.)

(Left ×35; right ×600.)

fected 1 to 3 months previously appeared to have considerable resistance to reinfection via the anterior chamber and this resistance seemed to be coincident with the appearance of skin sensitivity to histoplasmin.

The ocular reaction was thus analogous to that of immune-allergic animals upon reinfection with the tubercle bacillus. Ocular histoplasmosis, in fact, resembles ocular tuberculosis, not only in this apparent immunity but also in the granulomatous nature of the lesion and in its destructiveness. The organism is also believed to cause benign pulmonary calcifications almost identical by X-ray examination with those of tuberculosis.

C. HISTOLOGIC STUDY

Two routine histologic sections were made of each eye, the first stained with hematoxylin and eosin, and the second either by the Bauer technique[24] or by the periodic-acid method developed by Hotchkiss, McManus,[25-26] and others. The two latter methods are used to stain polysaccharides and will stain the yeast form of Histoplasma capsulatum.

Miscroscopic study of the eyes removed during the first week after infection gives a
Fig. 14 (Day). Rabbit D-6. Two months. Iris, left eye. Note intracellular yeast cells in high-power photomicrograph (right ×600). (Left ×35.)
Fig. 15 (Day). Rabbit D-9. One month. Iris, right eye. In figure at lower right (×600) there are numerous intracellular yeast cells; at lower left (×600) there are fewer. The giant cell in figure at upper right (×600) contains possibly 1 or 2 organisms. (Upper left ×140.)

variable picture, dependent upon the degree of immunity and the size of the infecting dose. The less violently inflamed eyes show a few spores and a small amount of mycelial debris in the anterior chamber; a few polymorphonuclear and mononuclear white blood cells on the posterior cornea, on the anterior iris, and in the iris stroma; and an occasional intracellular phagocytosed yeast cell (fig. 11). The more violently inflamed eyes show marked exudate, debris, polys, spores,

and yeast-containing macrophages in the anterior chamber, and marked edema of the iris with a variable infiltration of the iris stroma and ciliary body with macrophages, other round cells, occasional epithelioid cells, and rare giant cells (fig. 12).

With the appearance of the iris nodules, a granulomatous picture predominates (figs. 13 and 14). In some eyes there is a nodular infiltration of the iris with round cells, epithelioid cells, and a few polymorphonu-
Fig. 16 (Day). Rabbit D-11, L.E., Two and one-half weeks. Note the spore in the lower left corner of the high-power photomicrograph. These are not often seen at this stage of infection. (Left ×35, right ×600.)

clear leukocytes. Yeast cells can be seen within mononuclear wandering cells (figs. 13 and 14). In other eyes there are, in addition, many giant cells in some of which large numbers of yeast cells can be seen, apparently in various stages of digestion (fig. 15). There is considerable tissue destruction, usually beginning 4 to 6 weeks after infection, and, in many eyes, there are abscesses of cornea, iris, or ciliary body (fig. 16).

Two to 3 months after infection while the clinical signs of inflammation are subsiding, in addition to glaucomatous or phthisical changes, the eyes still show extensive round-cell infiltration of the anterior uveal tract and a few polymorphonuclear leukocytes. Some eyes have localized abscess of the iris or ciliary body, characterized by central necrosis and peripheral collections of round cells, epithelioid cells, giant cells, and yeast-containing macrophages, with a
Fig. 17 (Day). Rabbit D-17. Iris, left eye. Three months. Abscess with necrotic center and peripheral granuloma.

few polymorphonuclear cells scattered among them, not unlike the lesions of experimental ocular brucellosis (fig. 17). Most of the eyes examined at 3 months or later have extensive round-cell infiltration of the uvea without visible giant cells, and with few epithelioid cells. They present the picture of a nonspecific subsiding granulomatous inflammation (fig. 18). Phagocytosed

The injection of Histoplasma capsulatum into the anterior chamber of rabbit eyes produces a destructive granulomatous anterior uveitis closely resembling tuberculosis in its clinical appearance, but apparently self-limited in course. Systemic infection in rabbits may result in ocular involvement. Infected animals, as in tuberculosis, tend to develop resistance to reinfection and become
Fig. 18 (Day). Rabbit D-18. Iris and cornea, left eye. Three months. Subsiding granuloma.

yeast cells are seldom seen in the late stages, yet from one eye in which no organisms were visible by microscopy, they were recovered by culture six months after infection.

COMMENT

What bearing do the foregoing fragmentary data have upon the possibility of human ocular histoplasmosis?

It is credible from the work of Furcolow, Bunnell, Christie[21,12] and others that a non-fatal form of systemic histoplasmosis exists in human beings. Four patients with acute uveitis have now been observed, all of whom had skin sensitivity to histoplasmin and benign pulmonary calcification, yet had negative results from other routine clinical studies. In these patients the existing evidence points to the possibility that histoplasmosis was the cause of their ocular infection.

skin allergic to an extract derived from the infecting organism. The infection tends to subside and the organism to disappear from the eye following the development of skin sensitivity to histoplasmin. These facts are circumstantial evidence in support of histoplasma uveitis.

On the other hand, there is as yet no direct proof that the organism can produce subclinical or recurrent human infection anywhere in the body. There is no direct proof that the disease causes uveitis in human beings. The final proof must be the isolation of the fungus from the suspected case. There are to date insufficient data as to the duration of viability of the organism within the rabbit eye, but the evidence indicates a steadily decreasing viability which parallels the clinical course of the experimental disease. It is noteworthy, however, that the fungus was recovered from a clinically quiescent eye 6 months after infec-

tion. If the human disease exists and is analogous to the rabbit infection, the organisms and typical lesions are likely to be found only during the acute phase. Further clinical and histologic study of Histoplasma capsulatum as a possible cause of ocular disease is necessary in order to distinguish it from other causes of granulomatous uveitis.

SUMMARY

1. A brief review of the history of systemic infection with Histoplasma capsulatum has been made.

2. A significantly higher percentage of patients with uveitis reacted positively to skin testing with histoplasmin than of patients without uveitis. Four of these patients had a positive skin test to histoplasmin, pulmonary calcification, and uveitis as the only positive clinical findings.

3. Rabbits can be infected via the anterior chamber with Histoplasma capsulatum and develop a granulomatous anterior uveitis which is apparently self-limited in course.

HISTAMINE AND UVEAL INFILTRATION*

T. F. SCHLAEGEL, JR., M.D.

Indianapolis, Indiana

Because of the importance of allergy in the etiology of uveitis it was considered desirable to determine what histologic effect the ocular injection of histamine has upon the attraction of leukocytes.

A review of the literature indicates that histamine is not chemotactic for leukocytes although not all experiments along this line are in agreement.

In 1921, Wolf[1] published the results of her study on the influence of chemicals upon the chemotaxis of leukocytes in vitro. She found that histamine was strongly and positively chemotactic in molecular concentrations of over 0.000,025 percent. In 1922, Bloom[2] reported on the reaction of the cat to histamine dihydrochloride. He found practically no difference between the effects produced by injections of histamine in physiologic saline and of physiologic saline alone. Also glass tubes containing the histamine did not attract leukocytes either in vivo or in vitro. In 1923, Wolf[3] continued her studies on chemical inflammation, this time in vivo, and concluded that histamine produces a marked inflammatory reaction in frogs and mice.

In 1928, Grant and Wood[4] said that, since it seemed impossible to reconcile these conflicting results, they repeated Wolf's observations on the frog and made others on the rabbit and on human skin. Throughout their experiments they used 0.5-percent histamine acid phosphate dissolved in physiologic saline with the addition of sodium hydrate immediately before use to give a pH of 7.3. As a control a phosphate buffer solution of the same pH was employed.

They found that in frogs the mesenteric circulation remained active, no diapedesis of red cells took place, and no emigration of leukocytes could be detected until after 80 to 227 minutes, at which time emigration was found in mesenteries irrigated with phosphate solution alone or in those allowed to become dry.

In experiments on human beings, histamine was pricked into the skin and, when the vascular reaction was at its height, 20 minutes later, sections showed no leukocytic migration. In another subject the local reddening and whealing was maintained for 9 hours by pricking histamine into the same spot every 40 minutes. No increase in leukocytes was found except along the needle tract. The experiment was repeated and maintained for 25 hours with a control of phosphate solution. Microscopic examination failed to differentiate the two, there being leukocytes along the needle tract in both cases.

In 1928, Findlay[5] inoculated rabbits intravenously with staphylococci, streptococci, or pneumococci, 24 hours after several intradermal injections of histamine. Polymorphonuclear leukocytes were found diffused throughout the area injected with histamine, while in the area injected with a control of phosphate solution they were few and far between. Findlay's experiments thus indicate that histamine may act by favoring the localization of bacteria.

In 1934, Morgan[6] used histamine acid phosphate in a physiologic solution of sodium chloride on guinea pigs, rabbits, dogs, and human beings. An attempt was made to produce an inflammatory reaction in the rabbit by applying histamine by various methods. The conclusion was reached that histamine, when repeatedly instilled into the conjunctival sac, applied to the intact, burned, scratched, or cut skin for as long as 72 hours, or repeatedly injected into the muscle of the rabbit, does not produce an inflammatory reaction.

Another experiment consisted of producing a wheal with histamine and one of equivalent size by the injection of a physiologic solution of saline. Microscopic examination failed to demonstrate any difference between the areas into which the saline solution was injected and the areas in which wheals were produced by histamine.

Both tissues showed a diffuse infiltration of leukocytes with a slight concentration of white cells around the point of injection. Since there was a rapid increase of fluid in both cases, Morgan felt that the tearing and distortion of the cellular structures liberated products of tissue disintegration.

In 1935, Moon[7] reported experiments following the technique of Wolf and with modifications of it in vitro and did not note increased migrations of leukocytes toward inert substances containing various concentrations of histamine.

Moon then performed experiments to obtain further evidence on this point in vivo. Cylindric bits of elder pith of uniform size were cleared of soluble substances and then saturated with a physiologic solution of sodium chloride containing histamine phosphate in a 1:10,000 solution and were implanted in animal tissues through a canula. Some were introduced into the peritoneal cavity and others into the loose subcutaneous areolar tissue. In every instance a bit of elder pith saturated with physiologic solution of sodium chloride was similarly implanted as a control. Plugs saturated with histamine were implanted in 9 monkeys, 8 cats, and 4 guinea pigs. After from 6 to 24 hours the animals were killed and the reaction about the histamine pith was compared to that of the control.

In every instance, there was a marked zone of congestion about 2 cm. in diameter surrounding the pith saturated with histamine, but none about the controls. Microscopic examination revealed numerous leukocytes about both test and control piths. There was no evidence of active invasion of the pith by cells, and leukocytes were apparently as numerous about the control piths as about the ones containing histamine.

Moon also concluded that the evidence indicated that some product of cellular injury, other than histamine, is responsible for the local attraction of leukocytes.

Soon afterwards Menkin[8] demonstrated a factor in inflammatory exudates. This factor was later found to be a crystalline nitrogenous substance and was called leukotaxine.[9] It is capable of increasing capillary permeability and of attracting leukocytes. Within 15 to 30 minutes following its intracutaneous inoculation, polymorphonuclear leukocytes accumulate in abundance in the lumen of small vessels and then soon migrate actively into the extracapillary spaces.[10] Menkin gave repeated evidence that leukotaxine was not histamine and in no way related to it.[11-13]

In 1942, Rigdon[14] reopened the question of the chemotactic property of histamine. Using histamine phosphate diluted in saline to 1:1,000 to 1:8,000, he found that polymorphonuclear leukocytes were present in the extravascular tissues of the rabbit usually within an hour following the injection. The number of these cells appeared to increase during the following 4 to 5 hours and then to decrease. Control experiments apparently were not done, so Rigdon's conclusion that histamine phosphate was the chemotactic agent is to be questioned.

EXPERIMENTS

Although a review of the literature indicates that histamine has no unique chemotactic properties, it was decided to extend such experimentation to rabbit eyes. The problems of allergic uveitis focused attention on the reaction in the uvea. The uvea is prone to develop a cellular infiltration. For example, an injection of horse serum into the vitreous of normal rabbits results in cellular infiltration that is confined almost entirely to the uvea.[15]

PRELIMINARY TESTS

PART 1

The effect of two readily available strengths of histamine acid phosphate were compared (ampule form, 0.275 percent and vial form, 0.055 percent). Eight rabbits, divided into two groups, received injection of 0.1 cc. of the ampule or vial strength into the vitreous. After killing the animals by air embolism, the eyes were enucleated at 6 hours and at 1 week.

Clinical observations. One and one-half hours after the injection of either strength of histamine, a moderately severe chemosis was present. The pupils were contracted to a diameter as small as 2 mm. (The average apparent diameter of the pupils of 64 normal rabbit eyes under the same conditions of illumination was 7 mm.) After 4 hours the chemosis and miosis were unchanged, but at 6 hours there was beginning abatement.

Ophthalmoscopy at this time revealed haziness of the vitreous and slight dilatation of the retinal vessels. After 24 hours, the pupils were normal in size and the chemosis almost gone. The fundi showed no definite changes. Four days later the eyes were normal and remained so until the enucleation at 1 week.

Microscopic study. No significant histopathologic features were noted in any of the eyes.

PART 2

In this second experiment the vial strength (0.055 percent) was used and repeated injections were employed to determine whether it was possible to attract leukocytes by means of repeated injections of histamine. Six rabbits each received 0.1 cc. in the vitreous of the right eyes 7 mm. behind the limbus in the 12-o'clock meridian. The left eyes served as untreated controls. Such injections were given regularly on Monday, Tuesday, and Wednesday. Two rabbits were killed on Thursday for each of 3 weeks.

Clinical observations. In general the reactions in the anterior ocular segment of the right eyes were similar to those recorded in Part 1. Some signs of iritis, such as blurring of the iris pattern, were observed early. It was soon impossible to see the fundi because of clouding of the media.

Repeated injections caused changes in the lens producing posterior opacities while the vitreous was made very hazy. An increase of mucoid conjunctival discharge was common. In general the reaction to each injection of histamine became less as the experiment progressed, although definite evidence of endophthalmitis developed in some of the eyes.

Microscopic study. No significant differences were found between the 1, 2, and 3-week periods. A moderate infiltration of polymorphonuclear leukocytes was seen external to the sclera and in the region of the injection site, but the main finding was of endophthalmitis. A moderately heavy collection of polymorphonuclears was seen in the vitreous, lying especially behind the lens, over the ciliary body, and internal to the retina. A minimal accumulation of mononuclear cells in the choroid of some of the eyes was considered to be of no significance because: (1) such an infiltration is seen occasionally in the eyes of apparently normal rabbits, (2) such an infiltration in the presence of a severe endophthalmitis is to be expected.

MAIN EXPERIMENT

To subject the question of whether the uvea will react to histamine by a cellular infiltration to a more refined test, an attempt was made to place the fluid in the suprachoroidal space in direct contact with the choriod, and to study the histologic response at frequent intervals from 15 minutes to 3 days.

This time a control solution was made by adding 0.066 M. phosphate buffer of pH 7 to distilled water to make a solution that had a pH of 6.81 after autoclaving. The 0.275-

percent histamine acid phosphate was diluted with the phosphate buffer and distilled water to a strength of 0.055 percent and its pH brought up to the same level by the addition of a few drops of 10 percent NaOH. These two solutions were cultured before use and found to be sterile.

Under pentothal anesthesia an anteroposterior incision was made through the sclera over the pars plana. A beveled 23-gauge needle with blunted tip was introduced with the bevel hugging the inside of the sclera and was passed posteriorly for 5 to 8 mm. Where the injection of the 0.1 cc. was made.

Eighteen rabbits were used. Histamine was injected into the right eyes and the phosphate control into the left eyes. Two at a time the rabbits were killed by air embolism and their eyes enucleated at 15 and 30 minutes, at 1, 2, 4, and 6 hours, and at 1, 2, and 3 days.

Clinical observations. Clinically chemosis and miosis were observed in both eyes, but they were usually more pronounced in the right eyes injected with histamine.

Microscopic study. There is no significant histopathologic differences between the right eyes injected with histamine and the left eyes injected with the control solution except for more edema in the ciliary region of the histamine injected eyes. The following chronological survey of the more important histologic features, therefore, will consider both groups together and point out only the changes with time. The irides of most of the eyes of all stages present a bulge suggestive of iris bombé, although no evidence of posterior synechias is noted.

15 and 30 minutes

Suprachoroidal hemorrhage and detachment of the choroid are found at this period and in most of the eyes of the following stages.

1 hour

There is added a definite edema of the ciliary body, especially the processes. Chemosis of the conjunctiva is prominent and is accompanied by an infiltration of polymorphonuclear leukocytes.

4 and 6 hours

There are large cysts on the ciliary processes filled with edema fluid. Polymorphonuclear leukocytes are found outside the sclera and in its superficial lamellas. There are also a few polymorphonuclears in the suprachoroidal space, but those in the chemotic conjunctiva are beginning to be replaced by large mononuclear cells and fibroblasts.

1 day

At 1 day there is added definite round-cell infiltration of the pars plana and most of the choroid has small flat areas of mild lymphocytic infiltration.

2 and 3 days

The reaction appears to be waning. There are a few round cells in the ciliary body and choroid and a severe congestion of the ciliary processes.

No difference in cellular infiltration between the histamine and control eyes is noted at any stage.

COMMENT

A number of investigators have studied the effects of histamine upon the pupil and upon the intraocular pressure,[16-19] but as far as I know Alajma and Friedenwald are the only ones who have reported microscopic findings.

After the injection of histamine into the vitreous, Alajma[20] found an intense plastic uveitis which, on sectioning, showed an area of infiltration containing large numbers of eosinophils.

Friedwenwald[21] injected histamine into the eyes of dogs, cats, rabbits, and monkeys in an experimental study of acute congestive glaucoma. He found a marked edema of the ciliary body with extravasations of serum and fibrin about the capillaries just beneath

the epithelium. The ciliary processes were much swollen, especially at their tips, which were sometimes distended so as to form great bags filled with serum. The irides showed varying degrees of edema, usually less intense than that found in the ciliary body. Coagulated serum was found in the anterior, posterior, and vitreous chambers. In some instances there was slight bullous keratitis, and often marked conjunctival edema. Friedenwald did not mention the presence of wandering cells and the sections photographed do not indicate their presence.

Although our experimental methods differed, many of the features described by Friedenwald were observed.

The use of rabbits as experimental animals might be criticized. Darsie and others[22] found that, after the intradermal injection of various strengths of histamine diphosphate, no wheals developed in guinea pigs, rabbits, and cats, but they did develop in dogs, goats, and man. In the first group, not developing wheals, histamine results in vasoconstriction, while in the second it produces vasodilatation.

It is probable that a vascular reaction is the fundamental response to sensitization. This vascular reaction, however, is one of arteriolar constriction with stoppage of circulation and the migration of leukocytes, while histamine, in man, produces an active hyperemia by arteriolar and capillary dilatation.

From our review of the literature there was no evidence that the various animals, including man, showed any differences in the leukocytic response to injections of histamine. The consensus appears to be that histamine in itself does not attract leukocytes in any of those animals.

Histamine is commonly incriminated as the cause of allergic reactions. Although histamine undoubtedly plays a role in some allergic responses, it must be remembered that many other factors are involved. In fact, to explain the many different manifestations of allergy it can be assumed either that some

toxic agent is liberated, different for the various types of allergic response, each to produce its own special effect, or that the specific antibody permits the antigen to exert its own effect upon the sensitized cell.[23] This conception postulates unknown allergotoxins in addition to histamine.

The question of why wandering cells were attracted, although in small numbers, by both the histamine and the buffer control, seems to be answerable by one or both of two mechanisms. It is possible that the distention by fluid liberated a product of cellular injury, such as leukotaxine, which then attracted leukocytes; or it is likely that bacteria were introduced either at the time of the operation or subsequent to it. The fact that wandering cells were much more common in the main experiment, in which an incision was made with a knife, than in the first experiment, where the injection was made by a small needle, seems to indicate that the larger opening may have predisposed to infection.

SUMMARY

Because of the importance of allergy in the etiology of uveitis it was considered desirable to determine what histologic effect the ocular injection of histamine has upon the attraction of leukocytes. A review of the literature indicated that histamine is not chemotactic for leukocytes and this conclusion was confirmed for rabbit eyes.

Histamine acid phosphate was injected into the suprachoroidal space of the right eyes of 18 rabbits and a phosphate buffer control of the same pH into the suprachoroidal space of their left eyes. Microscopic study after periods ranging from 15 minutes to 3 days indicated no difference in the degree of cellular infiltration found.

It may be concluded that 0.055-percent histamine acid phosphate is not positively chemotactic for leukocytes and does not produce a uveal infiltration in rabbit eyes.

RETINITIS PIGMENTOSA ASSOCIATED WITH GLAUCOMA*

Samuel Gartner, M.D., and Abraham Schlossman, M.D.

New York

The association of retinitis pigmentosa with glaucoma was observed by us in several clinical cases and pathologic specimens. This raised the question whether the two diseases were coincidental or whether they bore a relationship to each other. The literature on the subject was found to be meager, but indicated that others have also felt that glaucoma was in some way related to retinitis pigmentosa. The migration of pigment is an outstanding characteristic of retinitis pigmentosa. Since the presence of pigment in the angle of the anterior chamber has been stressed as a possible etiologic factor in glaucoma, it was hoped that a careful study of these cases would shed some light upon this problem.

Retinitis pigmentosa is an important disease for it causes blindness sooner or later to all who suffer from it. When combined with glaucoma, this blindness occurs sooner. Our knowledge of retinitis pigmentosa is very limited, and our therapeutic results are very close to zero despite many attempts, including the recent suggestions of the Russians for the use of tissue extracts.

Retinitis pigmentosa has many peculiarities. It usually appears as an hereditary and familial disease with several different forms of heredity which will be discussed later in this article. It may be the only disease in otherwise healthy people. It may be associated with other ocular disorders, such as myopia or macular hole.[1]

Retinitis pigmentosa is frequently associated with other systemic disorders, particularly deaf-mutism, and occasionally with defects of the central nervous system, mental retardation, and idiocy. The Laurence-Moon-Biedl syndrome is an atypical retinitis pigmentosa with mental retardation, polydactyly, and pituitary disorders, such as obesity, and hypogenitalism.

LITERATURE

In 1862, Galezowski[2] described the first case of retinitis pigmentosa associated with glaucoma. Schnabel,[3] in 1878, published a case of acute glaucoma in a patient with retinitis pigmentosa and described the pathologic findings in the enucleated eye. The literature on the subject and 38 cases of glaucoma associated with retinitis pigmentosa were studied, and are outlined in Table 1. A large number of the cases were reported by the Russians who seem to have been particularly interested in retinitis pigmentosa. Among the papers which give a good review of the subject are those by Schmidhauser,[16] Mueller,[20] and Kotliarevsky.[27] Leber[29] and Peters[30] have written short reviews. Julia Bell[31] in her monograph on inheritance in retinitis pigmentosa has collected from the literature seven pedigrees showing an association with glaucoma.

Of the cases reported, 15 were apparently chronic simple, 7 inflammatory, 5 acute, and 3 absolute glaucoma. Two more cases were probably chronic simple glaucoma, and in 6 instances it was not possible to determine the type. Some of the cases of retinitis pigmentosa were atypical. Since many of the cases were described before the advent of the Schiøtz tonometer, it is difficult to know whether some of those reported really suffered from glaucoma. Optic atrophy in eyes with deep cupping may resemble glaucomatous excavation.

On the other hand, it is well known that the ophthalmoscopic picture of retinitis pigmentosa may be simulated by other conditions, such as, syphilitic and other forms of chorioretinitis, and trauma. The increased

tension in some cases in the literature may have been secondary to other ocular diseases. Since most of the reports were made before tonometry was in general use, the individual cases in the literature are not discussed, but are only outlined in Table 1. Conclusions will be drawn from the more recent cases and those described in this paper.

CASE REPORTS

Eight cases were collected and three of them were examined histologically.

CASE 1

History. J. C., a man, aged 30 years, was a patient in Dr. Boyes's service at the New York Eye & Ear Infirmary and is reported

through his kind permission. Retinitis pigmentosa was diagnosed at the age of 14 years. He developed glaucoma at 20 years of age, and surgery was performed at another hospital for this condition.

Eye examination. Vision was light perception in both eyes with fair projection. The right pupil was large, the lens opaque, and the iris tremulous indicating a dislocated lens. The left pupil was small and distorted. There was some lens opacity. The fundi were not visualized at this time. The tension in the right eye was 50 mm. Hg (Schiøtz) and in the left, 20 mm. Hg. The dislocated lens was removed from the right eye, but the tension remained elevated. Prostigmin and mecholyl controlled the tension and, since that time, it has been maintained with pilocarpine.

Family history. The patient's parents were first cousins. Two brothers have retinitis pigmentosa but no glaucoma. Three other brothers are normal. The patient posed the question whether he should have any children. We do not have sufficient data to know whether the inheritance is autosomal recessive or sex-linked recessive. If his maternal grandfather had suffered from retinitis pigmentosa, the disease probably would be sex-linked. Since his father and mother were first cousins, it is possible that the condition is an autosomal recessive. At all events, the only safe course was to advise him against having children.

Case 2

History. N. K., a man, aged 41 years, a patient at Montefiore Hospital, had suffered from night blindness since childhood. A diagnosis of retinitis pigmentosa was made in 1941 when he was 33 years old. He developed tuberculosis in 1944. In 1945, while at Montefiore, bilateral glaucoma was diagnosed.

Eye condition. At that time, the intraocular tension was 48 mm. Hg (Schiøtz) in the right eye, and 45 mm. Hg in the left. Vision was : R.E., 15/20; L.E., 15/25. The visual fields were constricted. The retina in

both eyes showed typical bone corpuscle pigment accumulations, narrow blood vessels, and atrophy of the optic nerve.

Since miotics did not control the tension, bilateral iridencleises were performed. Following surgery, the anterior chambers remained very shallow. Both irides were vascularized and patches of iris atrophy were visible. The pupils were drawn up and a small filtering bleb was present in each eye. The tension was 25 mm. Hg in both eyes. Corrected vision was : R.E., 15/100; L.E., 15/70. He uses pilocarpine (2 percent) three times a day.

Case 3

This case is presented through the courtesy of Dr. Charles A. Perera.* The patient was originally one of Dr. Charles H. May's and was subsequently treated by Dr. Perera.

History. F. T., a woman, aged 36 years, gave a history of night blindness and poor vision for many years. Since early childhood, she suffered from a marked strabismus, which was corrected in 1933 with an excellent cosmetic result.

Eye examination in May, 1936, showed normal intraocular pressure and shallow anterior chambers. The fundi revealed marked narrowing of the vessels, pallor and blurring of the discs. The peripheral retina contained small irregular pigment deposits and small pigmented areas were scattered throughout the fundi. The visual fields of each eye were contracted concentrically to 15 degrees from fixation. Vision in the right eye was corrected to 15/30 with +3.OD. sph. ◡ +1.25D. cyl. ax. 105°, and the left eye to 15/25 with +3.0D. sph. ◡ +0.75D. cyl. ax. 85°

The patient returned one month later, in June, and stated that five days previously she had experienced blurring of vision lasting five hours. There was no evidence, how-

---

*This case was presented at the meeting of the Section of Ophthalmology, New York Academy of Medicine, May 16, 1943, by Dr. Perera.

ever, of recent ocular disturbance. Four months later, in October, 1936, she returned with an acute iridocyclitis in the left eye which became quiescent after four weeks of atropine and salicylate therapy. Her intraocular pressure was normal at this time.

In November, 1937, the patient suffered an acute attack of glaucoma in the left eye which became stony hard. Tension was reduced to nearly normal by repeated instillations of eserine and pilocarpine. Two days later, the tension in both eyes rose to over 85 mm. Hg. Miotics did not help, and a bilateral Lagrange operation reduced her tension to normal.

The patient was last seen in February, 1948, at which time the intraocular pressure was 18 mm. Hg in the right eye, and 25 mm. Hg in the left. Her visual fields have not contracted further during the last 10 years. Her corrected vision is: R. E., 20/40; L.E., 20/30. The reduction in visual acuity was probably due to some increase in the posterior central lenticular opacities.

CASE 4

This case and Case 5 were briefly included in a previous report[32] and are from the practice of Dr. Adolph Posner.

History. The patient, W. F., a man, aged 53 years, gave a history of night blindness and retinitis pigmentosa was diagnosed in 1936. At that time, his intraocular pressure was normal.

Following a head injury in January, 1940, he was unconscious for 5 or 10 minutes. After that, he began to see halos around lights and experienced foggy vision after reading. He was seen by Dr. Posner in January, 1940. The tension was 42 mm. Hg (Schiøtz) in the right eye, and 49 mm. Hg in the left eye.

Eye examination. Vision of the right eye was 20/20 with a −0.75D. sph. ⊃ +1.5D. cyl. ax. 180°, and 20/20 in the left eye with +0.25D. sph. ⊃ +0.5D. cyl. ax. 90°.

There was shallow cupping of both optic discs, which showed a yellowish tinge. The

blood vessels were approximately normal in caliber and, in the periphery of the fundus, there were pigment deposits of the bone corpuscle type. The fields showed ring scotomas.

The tension responded temporarily to pilocarpine, but two weeks after the institution of medication, an acute attack of glaucoma occurred in the right eye. Iridencleisis was performed on one eye in January, 1940, and on the other in February, 1940, and the tension became normal. In 1946, when the patient was last seen, the tension in the right eye was 15 mm. Hg and in the left eye 20 mm. Hg. The visual fields were further contracted.

CASE 5

History. N. F., a white woman, aged 38 years, was seen in 1940 with a history of retinitis pigmentosa of 20 years' duration. She had married in 1940 and two months after marriage she had a sense of heaviness over the right eye and blurring of both eyes. Within a week, she lost all vision in the right eye.

Eye examination. When she was seen in August, 1940, vision of the right eye was nil and with the left eye she counted fingers at 12 inches. The right eye showed conjunctival congestion, edema of the cornea, and a tension of 90 mm. Hg (Schiøtz). The left eye had a tension of 50 mm. Hg and was somewhat congested. There was bilateral horizontal nystagmus. The discs were yellow and the vessels narrow. There were some irregular pigmented areas in the periphery of the fundus.

Family history. Two of her sisters suffer from retinitis pigmentosa and one of them, three years older than the patient, also has glaucoma in the left eye. One brother and sister are normal. Her parents are normal.

We are indebted to Brig. Gen. R. O. Dart and Mrs. H. C. Wilder of the Army Medical Museum for Cases 6, 7, and 8, and these cases are presented with the kind permission of the donors of these specimens.

CASE 6

History. The patient (Accession 81319—contributed by Dr. E. C. Ellett) was a 26-year-old white woman. Both she and her sister had retinitis pigmentosa. Hyperopia was found at the age of six years. Since then, her vision had become progressively worse until now, at her 26th year, she had developed severe pain in her left eye following dilatation of her pupils. The tension in the eye was 50 mm. Hg (Schiøtz), and an iridectomy was performed. Three years later, the anterior chamber filled with blood following a bout of sneezing. Elevated tension returned with severe pain, and it was necessary to enucleate the eye.

Pathologic Examination

Gross. The specimen consists of a small eye measuring 20 by 20 by 19 mm. The cornea is cloudy. There is irregular pigmentation of the fundus. The lens is opaque, the optic disc is cupped, and the anterior chamber is filled with blood-stained exudate.

Microscopic (figs. 1 and 2). The scar of iridectomy does not appear in the sections examined. There is little edema of the basal layer of the corneal epithelium. The anterior and posterior chambers contain blood. There are peripheral anterior synechias. The iris is atrophic and there are hyalinization and vascularization of the pupillary zone. The ciliary body is also atrophic.

There is considerable irregularity of the pigment epithelium which is depigmented in some areas, while in other regions it is deeply pigmented. Large clumps of pigment appear in the retina. Retinal vessels show obliterating changes and perivascular deposits of pigment. The rods and cones have almost completely disappeared. There is a loss of the normal architecture with replacement by glial tissue. The hole in the nervehead apparently was the site of calcified drusen which were lost during the technical procedures. One section shows small basophilic-staining drusen at the edge of the hole. The lamina cribrosa is depressed.

Diagnosis. Retinitis pigmentosa, glaucoma, drusen in nervehead, and recent hemorrhage in anterior chamber.

CASE 7

History. G. I. (Accession 72718—contributed by Dr. William M. Scales), a woman, aged 57 years, was seen in 1934 and a diagnosis of bilateral retinitis pigmentosa was made. The patient was not seen again until two weeks prior to enucleation when she complained of suffering for the past 6 months with pain which was apparently due to glaucoma in her left eye.

Eye examination. There was moderate pericorneal injection and the cornea showed degeneration with the formation of bullae. Transillumination was unsatisfactory. There was a brown cataract through which no reflex was obtained. Tension in the left eye was 70 mm. Hg (Schiøtz) while that in the right eye was 24 mm. Hg. The anterior segment of the right eye was normal except for a generalized opacity of the lens. Since the left eye was painful and did not have any light perception, it was enucleated.

In June, 1946, after a right cataract extraction, the vision corrected to 20/40 and there was ophthalmoscopic evidence of retinitis pigmentosa. There was no family history of night blindness or poor vision.

Pathologic Examination

Gross. Firm eye measuring 24 by 23 by 22 mm. The clouded cornea has a peripheral zone of opacity. The anterior chamber is shallow and the lens cataractous. Posterior to the equator, the fundus is deeply pigmented. The optic disc is cupped.

Microscopic (fig. 3). There are peripheral anterior synechias. The iris and ciliary body are atrophic and the ciliary processes are flattened and hyalinized. The entire uveal tract is rather deeply pigmented. There are multiple chorioretinal adhesions where Bruch's membrane has disappeared. The retina is atrophied and gliosed, with loss of rods and cones.

Fig. 1 (Gartner and Schlossman). *Case 6.* This shows peripheral anterior synechias and the absence of pigment in the angle.

Fig. 2 (Gartner and Schlossman). *Case 6.* This figure also shows peripheral anterior synechias and the absence of pigment in the angle.

Fig. 3 (Gartner and Schlossman). *Case 7.* There are peripheral anterior synechias but no pigment in the angle.

There is hyalinization, occlusion, and perivascular pigmentation of retinal vessels. Masses of pigment are present in the retina, and there are numerous areas in which the pigment epithelium is flattened and depigmented, or has disappeared entirely.

It is only in the macular region that any of the normal architecture is retained and here there is marked loss of ganglion cells. The optic disc is deeply excavated and the lamina cribrosa is correspondingly depressed. There

dilated. There was absolute glaucoma. Tension in the right eye was 95 mm. Hg (Schiøtz), and in the left eye it was 17.5 mm. Hg. The left eye showed marked retinitis pigmentosa. Her father is alive and also suffers from retinitis pigmentosa.

Pathologic Examination

Gross. Firm eye measuring 24 by 23 by 23 mm. There is some peeling of the corneal epithelium. The pupil is dilated and eccentric.
Fig. 4 (Gartner and Schlossman). *Case 8.* This demonstrates the presence of anterior synechias, ectropion uveae, and iris cysts.

is an atrophy of the optic nerve and lymphocytic infiltration around the central vein. Embedded in paraffin and cut separately, the lens shows cataractous changes.

Diagnosis. Retinitis pigmentosa, glaucoma, cataract, and optic atrophy.

CASE 8

M. B. (Accession 78871—contributed by Dr. C. A. Veasey, Sr.), a woman, aged 41 years, was known to have retinitis pigmentosa since her early twenties. In December, 1941, she was blind in the right eye and the left eye had a field which contracted to within 10 degrees of fixation. The right eye had previously had iritis with a large synechia at the 4-o'clock position. The pupil was irregularly

There are numerous minute pigmented spots in the retina. The lens is opaque and the vitreous cloudy.

Microscopic. There are peripheral anterior synechias, vascularization of the anterior surface of the iris, and ectropion uveae (figs. 4, 5, and 6). The pigment epithelium is separated and serous exudate fills the resultant cystlike spaces. There are degenerative changes in the cortical fibers of the lens. The ciliary body is atrophic. The iris and ciliary body are sparsely infiltered by chronic inflammatory cells. Lymphocytes more densely infiltrate the choroid. Occasional drusen are seen on Bruch's membrane.

The retinal pigment epithelium is markedly flattened and in many areas it is depigmented.
Fig. 5 (Gartner and Schlossman). *Case 8.* High-power view of the section in Figure 4, showing the angle with peripheral anterior synechias and a small amount of pigment in the angle. The pigment epithelium of the iris shows cyst formation.

architecture, microcystic degeneration, and gliosis. Particularly in the peripheral portion of the retina, there are obliterative changes in the blood vessels with perivascular pigmentation.

The optic disc and lamina cribrosa are depressed. There is a little organizing inflammatory and hemorrhagic exudate in the vitreous chamber at the ora serrata.

Diagnosis. Retinitis pigmentosa, chronic uveitis, glaucoma, and cataract.

Between the choroid and the retina, foreign-body giant cells surround cholesterin slits which remain as evidence of old hemorrhage. The retina is partially detached by serous exudate and pigment-laden phagocytes beneath it.

Retinal rods and cones and their nuclei in the outer nuclear layer have disappeared and are replaced by gliosis. The inner retinal layers show considerable loss of normal

DISCUSSION

INCIDENCE AND TYPE

It is difficult to obtain data on the incidence of glaucoma in patients with retinitis pigmentosa. Many cases of symptom-free
Fig. 6 (Gartner and Schlossman). *Case. 8.* High-power view of the section in Figure 4, showing ectropion uveae. There is a delicate, newly formed membrane on the anterior surface of the iris.

chronic glaucoma are probably missed, particularly when the eye is blind. Seven out of the 8 patients reported in this paper suffered from congestive glaucoma and the eighth probably had congestive glaucoma.

Weiss[13] reported 1 case of glaucoma among 55 patients with retinitis pigmentosa. Schmidhauser[16] reported 5 cases of glaucoma among 180 patients with retinitis pigmentosa at the Tuebingen clinic, a percentage of 2.78 as compared with 0.73 percent for all glaucoma in the clinic. In the private practices of Dr. Mark J. Schoenberg and Dr. Adolph Posner, glaucoma was diagnosed in 3 percent of all cases. Two patients out of 20 with retinitis pigmentosa, or 10 percent, suffered with glaucoma. However, with such small numbers, it is better to avoid conclusions. Suffice it to say that it is the opinion of most authors, including Leber[29] and Verhoeff,[33] that the occurrence of the two diseases together is more frequent than one would expect if it were based on coincidence alone.

It is generally believed that the glaucoma is secondary to the retinitis pigmentosa. Still, glaucoma occurs in relatively few cases. The ocular hypertension occurs in cases which clinically appear no different from other cases of retinitis pigmentosa. The glaucoma is similar to the usual case of primary glaucoma. In Case 1, the increased tension may have been due to the dislocated lens but, 10 years previously, the patient had suffered from glaucoma which required surgery. It is interesting to note that, in Cases 3 and 8, there was an attack of iridocyclitis before the glaucoma was evident.

The action on the eye of toxic substances which accumulate from the degeneration of the retina and the pigment epithelium may be a factor in the development of the glaucoma. A toxic action on the meshwork of the angle may impair its function.

We really do not know how much of the drainage of the intraocular fluids takes place through the retinal and choroidal vessels. Sclerosis of these vessels is commonly found in glaucoma of all types. It is difficult to determine whether this is a cause or effect; or whether it compounds the damage.

PATHOLOGY

In the literature, we have been able to find only three reports of pathologic studies of eyes with retinitis pigmentosa and glaucoma. These are by Schnabel, Komarowitsch, and Henderson.[3, 11, 21] Komarowitsch reported that the posterior lens surface was covered by a glass membrane thicker than the lens capsule. It was grown to the iris as in "glaucoma and iridochoroiditis."

The pathologic findings in the three cases presented here are similar to those found in glaucoma and in retinitis pigmentosa. There was atrophy of the iris and ciliary body. Peripheral anterior synechias were always present. The lamina cribrosa had receded and and the optic discs were excavated.

In addition, there were areas of depigmentation and degeneration of pigment epithelium and in many areas of the retina, especially around the vessels, there were large pigment deposits (figs. 7 and 8).

There was a loss of the normal retinal architecture; the rods and cones had largely disappeared and were replaced by glial tissue. The other retinal layers were diminished in their cellular content, irregular in their arrangement, with glial proliferation throughout the retina. The macular retina was best preserved, and formed a striking contrast to the remainder. Pigment deposits were found in the retina in characteristic bone corpuscle shapes and surrounding the blood vessels.

Von Hippel[34] described two enucleated eyes with glaucoma and retinal findings similar to retinitis pigmentosa. However, many pathologic conditions of the retina and choroid simulate retinitis pigmentosa. Chorioretinitis, particularly the luetic type, and trauma, particularly with an intraocular foreign body, are among the more common offenders. Careful perusal of the histories in Von Hippel's cases makes one rather dubious
Fig. 7 (Gartner and Schlossman). Oblique section of the retina in a case of retinitis pigmentosa, showing the pigment deposits mainly above the vessels and a few irregular clumps of pigment.

whether they are true cases of retinitis pigmentosa.

He proposed the hypothesis that pigment accumulation in the angle was the cause of the glaucoma. As proof, he showed a picture of the chamber angle in one case with a considerable amount of pigment. Consequently, the belief has taken hold that the ocular hypertension in retinitis pigmentosa is caused by an accumulation of pigment in the trabeculum, mechanically blocking filtration.

The angles of the anterior chamber in the cases presented in this study were carefully examined (figs. 1, 2, 3, and 5). While pigment was present, the amount was not excessive nor even considerable. In one case, there was hardly any pigment at all in the trabecular spaces.

A survey was made of the anterior-chamber angles in a large number of slides from a variety of other cases. Pigment in the angle was found to increase with age and was present in larger amounts at the lower part of the angle. The normal Negro eye has considerable pigment in the trabeculum. Small amounts of pigment are common in glaucoma.

Malignant melanoma of the choroid with secondary glaucoma shows little or no pigment in the angle in most cases. We found only one case of glaucoma secondary to melanoma of the iris with a very heavy deposit of pigment in the trabecular spaces. The angle of the anterior chamber is open and there are no posterior synechias (fig 9).

Only in this particular case does it seem possible that pigment in the trabeculum may have been a factor in producing glaucoma. Even in this instance, we cannot be certain

Fig. 8 (Gartner and Schlossman). Flat section of the retina in a case of retinitis pigmentosa, showing the pigment deposits mainly above the blood vessels with some irregular clumps of pigment.

Fig. 9 (Gartner and Schlossman). Case of melanoma of the iris with glaucoma, showing an extensive deposit of pigment in the trabeculum without peripheral anterior synechias.
that some other mechanism, which produces glaucoma in the usual case of melanoma, was not operative in this one.

Gonioscopic studies in several of our cases of retinitis pigmentosa did not show any abnormal amount of pigment in the trabecular spaces. We believe that in the cases of retinitis pigmentosa and glaucoma, it is not a simple mechanical block of the angle by pigment which produces the glaucoma. It is possible that the dispersed pigment and the products from retinal degeneration are toxic to the trabeculum, alter its permeability, and thus produce glaucoma.

One finding is common to both retinitis pigmentosa and glaucoma; namely, sclerosis of the retinal vessels. While this condition may not exist in early cases of glaucoma, it is usually prominent by the time the eyes become pathologic specimens. Its influence on the course and development of both diseases is not clear.

The narrowing of the retinal vessels in retinitis pigmentosa was noted long ago and it was assumed by some that the retina became degenerated due to a spasm of the vessels causing a poor blood supply. Attempts have been made to widen these vessels by sympathectomy. That this type of approach was doomed to failure can be readily understood when these eyes are examined histologically. The vessels are narrow due to extensive sclerosis with endothelial proliferation and dense connective-tissue formation which usually has undergone hyalin degeneration. In these vessel walls, no muscle can be identified. Such a wall cannot conceivably be affected by sympathectomy. Only if there

were a muscular spasm narrowing the vessels could sympathectomy possibly widen them.

The impaired circulation in retinitis pigmentosa is apparently a result of the disease affecting the vessels. The perivascular accumulation of pigment may be a factor in causing the sclerosis. Early stages of retinitis pigmentosa are frequently seen in young people who have a rich retinal circulation. Among the aged, we see large numbers who develop narrow retinal vessels due to extensive arteriosclerosis without ever developing the picture of retinitis pigmentosa. Therefore, it does not appear likely that the arteriosclerotic process causes the retinitis pigmentosa. The reverse seems more probable.

A study of a disease in rats which resembles retinitis pigmentosa was reported by Bourne, Campbell, and Tansley.[35] They found that it was inherited as a recessive Mendelian character. Retinal degeneration began in the rods, then proceeded to the outer nuclear layer. Later, the pigment epithelium became degenerated apparently as a secondary effect. The subsequent wandering of the pigment into the retina gave the characteristic picture. These authors agree with Treacher Collins[36] that there is an abiotrophy of the retinal epithelium, and also with Ver-

hoeff[33] that it is not the choroidal changes which produce this disease.

HEREDITY

The pedigrees which have been collected from the literature by Bell[31] demonstrate that retinitis pigmentosa may be inherited in a number of different ways. Retinitis pigmentosa may be inherited as a dominant, partially dominant, recessive, or sex-linked recessive character. It is also possible that a gene for retinitis pigmentosa may be present in the y-chromosome and even cross over to the x-chromosome.[37]

In addition, it is possible that there are several recessive forms of the disease, each with separate genes. Thus, even from an heredity point of view, retinitis pigmentosa seems to represent several diseases. Primary glaucoma is hereditary in approximately 13 percent of the cases. Posner and Schlossman[38] recently reported a series of pedigrees of glaucoma families showing that, although the disease is dominant, there is a certain amount of lack of penetrance; also the possibility of recessive inheritance was not excluded.

Similar to its combination with deafness and myopia, the cases of retinitis pigmentosa and glaucoma may be inherited together as coincidental or associated defects. It is possible that the genes for these separate diseases are linked on the same chromosome. Glaucoma and retinitis pigmentosa may be a single hereditary syndrome similar to the Laurence-Moon-Biedl syndrome.

Of the seven reported pedigrees of retinitis pigmentosa and glaucoma, only two show glaucoma in more than one sibling. Blessig,[39] on the other hand, reported an interesting family tree which suggests that the occurrence of the combinations of both diseases is more than mere coincidence. Among 9 children, 2 sisters suffered from glaucoma and did not have retinitis pigmentosa, while 2 brothers and 1 sister suffered from retinitis pigmentosa without glaucoma. One of the siblings with glaucoma and all of those with

retinitis pigmentosa suffered from deafness. Bradbourne's[23] pedigree shows 5 sisters out of 9 siblings with retinitis pigmentosa. Three of them also had glaucoma.

Among the cases presented in this paper, Case 1 has 2 brothers with retinitis pigmentosa; Case 5 has 2 sisters with retinitis pigmentosa and 1 of them also suffered with glaucoma. Case 6 has a sister with retinitis pigmentosa, and the father of Case 8 had retinitis pigmentosa.

Unfortunately, we were not able to obtain enough data on any of our cases to determine the exact nature of the inheritance. The occurrence of only one disease in one member of the family and two diseases in other members is an interesting phenomenon. This is similar to the occurrence of arachnodactyly in some members of a family, dislocated lenses in other members, and a complete Marfan's syndrome in still other siblings.

Case 1 was concerned about having children. From the meager pedigree that is available on this patient, it is difficult to know whether the heredity is sex-linked recessive or autosomal recessive with the development of the disease as the result of the consanguineous marriage of his parents. We need to know whether his maternal grandfather had suffered with retinitis pigmentosa to decide whether the inheritance was sex-linked. Unfortunately, this information was not available. We advised him against having any children because of the possibility that the condition was sex-linked. It is important to know the mechanisms of heredity because patients are well aware of the hereditary nature of disease and the physician has the responsibility of giving eugenic information and advice.

ENDOCRINE

The pituitary gland has been implicated in retinitis pigmentosa, especially in the Laurence-Moon-Biedl syndrome. Some cases have pigmentary changes elsewhere in the body. Zondek and Wolfsohn[40] have stressed symptoms of pituitary involvement in some

cases of glaucoma. It is well known that the autonomic nervous system plays a role in the pathogenesis of glaucoma. Some think there is a relation between the vegetative nervous system and retinitis pigmentosa. These considerations, however, are so speculative that they are mentioned without discussion.

Undoubtedly, many cases of glaucoma remain undiagnosed in patients who are blind from retinitis pigmentosa. All cases of retinitis pigmentosa should be studied for early signs of glaucoma.

The appearance of retinitis pigmentosa is probably produced by a number of disease processes. The heredity and the course of the disease varies a great deal in different families. It is possible that the retinitis pigmentosa associated with glaucoma is different from the other forms of retinitis pigmentosa.

SUMMARY

Eight cases of retinitis pigmentosa associated with glaucoma are presented and the pathologic findings in three of these cases are described. Accumulation of pigment in the trabecular spaces with blockage of the filtration channels was not a factor in the development of glaucoma in these cases.

The possible etiologic connections between the two diseases are discussed. The role of toxic substances from the degeneration of the retina and pigment epithelium and sclerosis of the vessels is considered.

From an hereditary point of view, it is possible that the two diseases are linked together on the same chromosome and form a single hereditary syndrome.

UNILATERAL RETINITIS PIGMENTOSA*

REPORT OF A CASE

DAN M. GORDON, M.D.
New York

The occurrence of unilateral retinitis pigmentosa is one of the rarer events in ophthalmology. Beigelman,[1] in his review of the literature, in 1931, was able to collect only 10 cases, besides his own, which he felt fitted into this category.

He makes note of the fact that many writers have voiced doubt as "to the very existence" of this condition, and states, "Two objections are raised against cases reported as unilateral pigmentary retinitis; (1) The ophthalmoscopically and functionally normal eye might be affected in the future, particularly when the diagnosis is made on the basis of a single examination, or (2) the condition is not a true pigmentary retinitis but an acquired chorioretinal atrophy with pigmentation. Syphilis is often blamed."

Beigelman's own case was followed by him for over five years with no change in the "normal" eye and with increase in the severity of the affected eye.

REVIEW OF THE LITERATURE

Four other cases of unilateral retinitis pigmentosa have been reported since Beigelman brought the subject up to date in 1931. The complete list, including those noted by him is as follows:

1. Pedraglia (1865) a man, aged 36 years, with affected right eye.
2. de Wecker (1868) a girl, aged 15 years, with affected left eye.
3. Baumeister (1873), a man, aged 44 years, with affected left eye.
4. Dehrig (1882), a woman, aged 46 years, with affected right eye.
5. Gunsburg (1890) a man, aged 42 years, with affected left eye.
6. Gonin (1902) a man, aged 25 years, with affected left eye.
7. Nettleship (1907) a woman, aged 30 years, with affected right eye.

8. Hine (1924) a man, aged 34 years, with affected right eye.
9. Rossi (1926) a woman, with affected right eye.
10. Shoji (1926) a girl, aged 10 years, with affected left eye.
11. Beigelman (1931) a woman, aged 36 years, with affected left eye.
12. Agatston (1939) a man, aged 53 years, with affected right eye.
13. Agatston (1939) a woman, aged 45 years, with affected left eye.
14. Schupfer[2] (1937) a woman, aged 55 years, with affected right eye.
15. Schupfer[3] (1937) a man, aged 24 years, with affected left eye.
16. Gordon (1948) a man, aged 26 years, with affected right eye.
17. Bentzen[4] (1917) a woman, aged 30 years, with affected right eye.
18. Lowegren[4] (1948) a woman, aged 63 years, with affected left eye.
19. Dreissler[4] (1948) a woman, aged 53 years, with affected left eye.

It is noteworthy that Beigelman's case was the first of such a condition to be reported from this country and that but three others, including mine, have since been reported from the United States.

REPORT OF CASE

History. R. R., a 26-year-old white man, was first seen on June 11, 1946, when he stated that his eyes began tiring and tearing in 1944. He did not note any difficulty in darkness. He was in the Navy at that time and was examined by their medical officers on several occasions; finally, he was discharged in November, 1944, with a diagnosis of retinitis pigmentosa. He was seen at another eye clinic prior to his visit to the New York Hospital and was told that he had retinitis pigmentosa, which was more pronounced in his right eye than in his left.

Navy records. The patient has furnished photostatic copies of his Navy records, the pertinent data of which is, "Disability is not the result of his own misconduct and was incurred in line of duty. Vision 20/20 each eye on induction in the navy, October 23, 1940.

"This patient was admitted to the sick list September 4, 1944, from the staff of the hospital, complaining of difficulty in reading.
Fig. 1 (Gordon). The unaffected left eye.

Physical examination was essentially negative except for the eyes. Vision was: O.D., 10/20; O.S., 20/15. Pupils round, react to light and accommodation. Ophthalmoscopic examination of the right eye shows a small posterior polar opacity of the lens. The vitreous is clear. Examination of the fundus shows some attenuation of the arterioles. The disc is slightly pallid. In the entire periphery of the fundus there is a degeneration, proliferation and migration of pigment which over-lies the retinal vessels.

"Ophthalmoscopic examination of the left eye is essentially negative. Field studies of the right eye show a concentric contraction

Fig. 2 (Gordon). The affected right eye. Note the blurring of the disc and the marked attenuation of the vessels. The arteries are barely visible.
Fig. 3 (Gordon). Superior periphery of the right eye, showing the typical pigmentation.

mentation with one small particle of pigment on the disc, nasally.

L.E., media are clear, the disc is normal in color and outline, the vessels are normal, no tapetoretinal reflexes. There is one small patch of pigment superotemporally, which is not spidery in shape.

Slitlamp examination reveals an early central posterior subcapsular lens opacity on the right. No lens opacities on the left.

Field studies. R.E., constricted to from 5 to 10 degrees; L.E., full and normal. Careful search with small white and with colored targets, failed to reveal the scotomas described by the Navy.

DISCUSSION

The occurrence of the unilateral retinitis

to eight degrees. Field studies of the left eye show two small scotomas about 10 degrees in diameter in the extreme lower temporal quadrant and moderate concentric contraction. Routine laboratory examinations were negative and the spinal fluid Kolmer test was negative.

"The diagnosis of retinitis has been established."

Family history. This patient has gone into his family history very thoroughly and can find no evidence of the existence of any night-blinding disease in his ancestry. His parents were unrelated prior to marriage. He has two brothers and two sisters who have no visual complaints.

On physical examination here on June 11, 1946, his vision was: R.E. 20/70; L.E., 20/15 with J2 and J1, respectively. R.E., with a −0.5D. sph. ⊃ −0.25D. cyl. ax. 45°, he reads 20/30 on the Snellen chart. The external examination reveals no pathologic condition of note.

Fundus examination. R.E., there are some linear vitreous floaters. The disc is pale and somewhat blurred. The arteries are very attenuated. There is the typical golden metallic glinting reflex of the tapetoretinal diseases seen in the mascular area. There is dense midperipheral corpuscular shaped pig-

Fig. 4 (Gordon). A series of visual field charts, showing the progressive loss of visual field in the right eye, with essentially no change in the field of the left eye. (A) August 5, 1946, for 1/330 white. (B) August 14, 1947, for 1/330 white. (C) July 6, 1948, for 1/330 white.

pigmentosa (or a condition in every way similar to it) is chiefly of interest for two reasons. (1) Until recently the primary pigmentary degenerations of the retina have been considered as fairly well worked out and understood diseases, and (2) its occurrence runs counter to every etiologic theory that has been advanced thus far.

Atypical cases of primary pigmentary degeneration do occur and, with the exception of the condition now being discussed, are always bilateral. Hence, their existence has not conflicted with the various theories advanced to account for their etiology. All of these theories take into account a systemic etiology, whether it be diencephalic or abiotrophic. That either of these mechanisms can permanently affect only one eye is not conceivable. There would remain but one other explanation; trauma or disease of the afflicted one eye. Yet, neither of these conditions have been recorded as important factors in the histories of the cases reported. It is obvious that we have no satisfactory explanation for unilateral retinitis pigmentosa, and probably none for the bilateral form, either.

Agatston[2] states that "the suggestion of traumatic origin of the disease promoted by Wagenmann's experiments is not consistent with the statistics which show that retinitis pigmentosa following trauma is practically unknown."

Beigelman, in 1931, wrote in a similar vein and quoted A. L. Whitehead and M. H. Horning as "observing not a single case of bone corpuscle arrangement of pigment in the vast material of direct and indirect ocular injuries during the World War." He also stated that the literature does not contain a single convincing case of retinitis pigmentosa which was caused by or precipitated by trauma.

Beigelman went on to point out that Wagenmann, himself, described the changes produced, in his classical experiment of section of the ciliary arteries in rabbits, as resembling a healed chorioretinitis. This is a point which has been apparently overlooked by many who have concluded that Wagenmann produced a retinitis-pigmentosalike picture by his arterial sections.

The author has no further suggestion at present to add to the number of theories now confusing the literature as to the etiology of retinitis pigmentosa.

SUMMARY

A case of retinitis pigmentosa occurring in but one eye, with the other eye apparently normal, is reported, and the literature brought up to date.

525 East 68th Street (21).

OCULAR MANIFESTATIONS OF PRIMARY NASOPHARYNGEAL TUMORS*

DAVID C. BOYCE, M.D., AND NORMAN BOLKER, M.D.

Iowa City, Iowa

Ocular signs and symptoms are common in patients with primary nasopharyngeal tumors, but, as far as is known, there are only two reports on this subject in the American ophthalmic literature.[1, 2] Therefore, it seems worth while to report the results of a survey of the 44 cases of this type which have been seen in the University Hospitals during the past 15 years.

TYPES OF TUMORS

Tumors of the nasopharynx may be either benign or malignant. Among the benign types are fibroma, hemangioma, neurofibroma, lipoma, xanthoma, dermoid, teratoma, chondroma, and mixed tumors.

By far the most common of these is the fibroma; this tumor arises from the periosteum covering the bony walls of the nasopharnyx and usually occurs in young adults, developing in the years of puberty and spontaneously regressing during the twenties. It has a smooth, vascular structure which histologically resembles fibrosarcoma, but it never infiltrates or metastasizes. Its most common symptoms are nasal bleeding and obstruction.

Malignant neoplasms of the nasopharynx are relatively more common than non-malignant tumors. They are more often seen in males and occur more frequently in younger individuals than other malignant growths of the upper respiratory and alimentary tracts.[3] Godtfredsen[4] has pointed out that the most common site of origin of a primary malignant tumor of the nasopharynx is in the lateral wall, and it was his impression that about half of the malignant tumors arose from this portion. The second most frequent site was the roof and the least was the posterior wall of the nasopharynx.

Hayes Martin, however, claimed the tumors arise more often from the posterior wall in the region of the nasopharyngeal tonsil with the lateral wall less often involved.[3]

The most common form of malignant growth noted in the nasopharynx is the epidermoid carcinoma. Lympho-epithelioma, neuroblastoma, sarcoma, fibrocytoma, and adenocarcinoma are encountered in fewer numbers.

AGE AND SEX DISTRIBUTION

In this series of cases, the age and tumor type incidences agree in general with those reported by others (tables 1 and 2). The

Nonmalignant:

Juvenile fibroma of Ewing	7
Sclerosing angioma	2

Unknown: 1

distribution by sexes conforms to that usually reported, there being 25 males and only 9 females in this group.

SYMPTOMS

Characteristically, primary malignant tumors of the nasopharynx do not cause symptoms during the early stages of development. The patient comes for examination usually because of enlarged cervical lymph nodes, occasionally because of manifestations of intracranial involvement, and less often because of symptoms localized to the nasopharynx.[5] It is not uncommon to find that patients have received treatment for a variety of supposed diseases before a proper diagnosis is made. In our series, nasopharyngeal symptoms were more common than those from intracranial involvement, probably because nine cases of benign tumors are included in the series.

The cervical lymph nodes most frequently involved are those situated beneath the mastoid tip under the upper end of the sternocleidomastoid muscle. Auditory symptoms, such as tinnitus and deafness, are present early as the tumor is often located next to the orifice of the Eustachian tube. When the tumor erodes the base of the skull, cranial nerve palsies develop.

The tumor may infiltrate the parapharyngeal space or pass through nearby foramina, particularly those in the base of the skull. Frequently invasion is through the foramen lacerum whereby the tumor gains access to the region of the carotid artery, the cavernous sinus, and the sensory and motor nerves to the globe.

Of the cranial nerves, the abducens and trigeminal are most commonly affected. Once the tumor has reached the middle cranial fossa, it may grow forward through the superior orbital fissure into the orbit, thus giving rise to the various ocular complications such as optic atrophy, choked disc, and proptosis. Systemic metastases are seen in one third of the patients, the skeletal system being most often involved with the liver and lungs next in order.[6]

TABLE 3

SIGNS AND SYMPTOMS PRESENTED ON ADMISSION BY 44 PATIENTS WITH NASOPHARYNGEAL TUMORS

Signs	Number	Percent
Cervical lymphadenopathy...	24	54.4
Nasal obstruction..........	20	45.5
Epistaxis..................	20	45.5

Fullness in throat..........	4	9.0
Tinnitus...................	3	6.8
Sore nose..................	2	4.5
Speech defect..............	1	2.2
Swelling of face............	1	2.2
Pain in arm and chest......	1	2.2
Post nasal drip............	1	2.2

DIAGNOSIS

In our series, diagnosis was made by direct visualization of the tumor in all cases and proved by biopsy in all but one case. On admission, 54 percent of the 44 patients had palpable cervical nodes. Nasal obstruction, epistaxis, and poor hearing were present somewhat less frequently. Headache and ocular symptoms were noted in approximately 25 percent of the patients in this series. Dysphagia, facial pain, weight loss, hoarseness, and a variety of other symptoms were noted in decreasing numbers (table 3).

OCULAR MANIFESTATIONS

Thirty-two percent of the 44 patients developed ocular manifestations at some time

Fig. 1 (Boyce and Bolker). W. F., a 50-year-old man, with epidermoid carcinoma of the naso-pharynx. He had slight exophthalmos on the right, 5th-nerve paresis, 12th-nerve paralysis, and 7th-nerve paralysis.

during the course of their disease. Most of those showing ocular signs were found to have malignant tumors. The ocular signs and symptoms were multiple in 54 percent of the patients. Involvement of the abducens was most common, while oculomotor and trochlear nerve palsies were noted in fewer cases. There were four cases of unilateral proptosis (table 4).

CASE REPORTS

The following three cases are typical of those showing ocular manifestations:

Case 1. E. F., a white man, aged 50 years (fig. 1), was first seen in August, 1947, because of deafness and a feeling of pressure in the right ear. Transient diplopia had been noted in October, 1946. Pain over the right side of the face and enlargement of the right cervical lymph nodes had been present for five months.

At examination, he was found to have an epidermoid carcinoma of the right naso-pharynx which produced a small amount of exophthalmos of the right globe, paresis of the ophthalmic branch of the trigeminal

nerve, and paralysis of the hypoglossa nerve. Roentgenograms showed erosion o the base of the skull. This patient was give a course of roentgen therapy. He returneu a few months later showing a right facial paralysis and an exposure keratitis.

Case 2. K. A., a 13-year-old boy (fig. 2), was first seen in December, 1947, at which time he had had nasal obstruction for 13 months, episodes of epistaxis for 12 months, and proptosis of the left eye for 1 month. He was found to have a juvenile fibroma of the nasopharynx.

Roentgenograms of his skull did not reveal any erosion, and the tumor was presumed to have extended through orbital foramina into the orbit. He received roentgen therapy and no recent increase in symptoms has been noted 6 months after treatment.

Case 3. J. Y., a 3-year-old girl (fig. 3), was seen in 1940. Her parents gave a history indicating that she had had nasal obstruction, abducens palsy, frequent nose bleeds,

Fig. 2 (Boyce and Bolker). K. A., a 13-year-old boy, with juvenile fibroma of the nasopharynx showing exophthalmos of the left eye.

and proptosis of the right eye for several months.

On physical examination, she was found to have bilateral choked discs. No abdominal masses were noted. After microscopic examination, the tissue from the nasopharynx was diagnosed as neuroblastoma. The exophthalmos decreased following roentgen therapy. Two months later, an abdominal mass became evident. The patient died three months after admission.

Although the nasopharynx is an unusual primary site for neuroblastoma, cases have been known to occur there, and the growth characteristics as seen at the time of exploration through both an orbital and nasopharyngeal approach would indicate this to be true in this instance.[6]

TREATMENT

The most generally accepted method of treatment of malignant tumors of the nasopharynx is roentgen irradiation. Radium is not often used as it is difficult to apply to this site. Since the lesions are deep, multiple ports are needed to deliver an adequate tumor dose without over-irradiating the skin. Highly penetrating beams, as produced by high voltages and heavily filtered rays, are essential to successful treatment. Care should be taken to shield uninvolved radiosensitive tissues such as the pinna of the ear and the structures of the anterior segment of the eye.

At this hospital the treatment of a malignant nasopharyngeal tumor varies, depending on the proposed effect of treatment, whether curative or palliative, and the response of the tumor to irradiation. A curative effort is made in every case without evidence of distant metastasis.

Skull involvement as demonstrated by roentgenograms is not considered a definite contraindication for a curative effort. The best results are obtained with patients who report for treatment before the appearance of enlarged cervical nodes.

A tumor dose of approximately 3,500 to 5,000 r is desired, and this is achieved by the

Fig. 3 (Boyce and Bolker). A 3-year-old girl with neuroblastoma of the nasopharynx. She showed proptosis of the right eye, bilateral choked discs, and paralysis of the 6th nerve on the right. She died three months after admission.

administration of 2,600 to 3,400 r in air to each of 2 or 3 fields. In a centrally located lesion, 4 fields may be used, both right and left lateral nasopharyngeal and right and left oblique maxillary fields. In addition to the primary tumor, the involved cervical lymph nodes are also treated.

Palliative treatment is administered to relieve pain and nerve palsy, decrease exophthalmos, nasal obstruction and epistaxis, and to improve the general condition of the patient when the extent of the disease precludes a cure. Treatment is stopped when these objectives are attained.

Following treatment the primary lesion usually regresses rapidly, the only evidence of involvement being a defect of the pharyngeal mucosa which closes over with epithelium. Ordinarily there is no recurrence at the primary site, but rather in the lymph nodes. Pain from nerve involvement is often relieved after the first few treatments. The radiation reaction of the skin is transient and leaves minimal changes with properly given treatment.

With two exceptions, all of the benign

tumors in our series were juvenile fibromas. The exceptions were sclerosing angiomas, a tumor which is histologically closely related to fibromas. Since juvenile fibromas regress spontaneously in a few years after puberty, the object of treatment is not so much eradication of the tumor as restriction of its harmful effects until they are physiologically remedied. Efforts are made to decrease the frequency of epistaxis and expansion of the mass. Surgical extirpation is contraindicated due to the exceedingly vascular nature of the tumor. In fact, biopsy may cause severe hemorrhage.

Again, external irradiation is the treatment of choice, the dosage varying with the response to irradiation and ranging from 1,000 r to 2,500 r tumor doses.

COMMENT

Tumors of the nasopharynx, while uncommon, should none the less be kept in mind by the ophthalmologist for he may be the first to be consulted by the patient. If he is aware of the usual findings in this type of tumor, he may make the diagnosis early and give the patient the benefit of more prompt treatment.

SUMMARY

Carcinoma of the nasopharynx is rarely diagnosed correctly early because of the silent nature of the primary tumor and the difficulty of adequately examining the area. Usually the secondary manifestations of the tumor achieve prominence before diagnosis is made.

Forty-four consecutive cases of nasopharyngeal tumors seen over the past 15 years are reviewed; 34 were malignant, 9 nonmalignant, and 1 of unknown type. Thirty-two percent of the cases showed ocular signs or symptoms at some time during the course of the disease. Abducens palsy was most common of this group. Proptosis and lesions of the optic, oculomotor, and trochlear nerves were present in lesser numbers. When ocular manifestations were present, the prognosis was poor. The treatment of choice has been roentgen therapy.

A STUDY OF THE EFFECT OF RETROBULBAR ANESTHESIA ON THE OCULAR TENSION AND THE VITREOUS PRESSURE*

HAROLD GIFFORD, JR., M.D.

Omaha, Nebraska

Ever since Elschnig[1] popularized the use of retrobulbar anesthesia in 1925 it has been known that the ocular tension is lowered by this procedure. Atkinson[2] has pointed out that there tends to be a deepening of the anterior chamber. Icaza[3] and Levett[4] suggested the use of retrobulbar injection to relieve pain and lower the tension in acute glaucoma.

The studies of vitreous loss by Wright,[5] Lancaster,[6] Kirby,[7] and myself,[8] have shown that there is a posterior segment pressure which is an important problem in cataract surgery. Elschnig, DeGross,[9] Dunphy,[10] Greenwood and Grossman,[11] and my brother, Sanford Gifford,[12] all have reported that the use of retrobulbar injection reduces the amount of vitreous loss in cataract surgery.

Ferrer,[13] Bothman,[14] and Lombardo,[15] checked the ocular tension before cataract operations but made no special separation of ocular tension and vitreous pressure. Ferrer believed that a high preoperative tension was a danger signal. Lombardo demonstrated that a lower preoperative tension was a good prognostic sign. Bothman reported only 1 case of vitreous loss in 23 cases with a high preoperative tension, and 2 cases had inverted flaps or low vitreous pressure at the time of operation.

Ferrer[16] in a later paper pointed out the fact that ocular tension did not cease when the chamber was opened. He noted that some eyes had an increased tension but he did not attempt to analyze the difference between ocular tension and vitreous pressure.

It seemed to me that a detailed study of the mechanism that produces this lowering of intraocular pressure might bring to light some interesting physiologic facts which might lead to safer cataract surgery, and perhaps to a better understanding of the etiology of glaucoma. I have been working on a method to produce complete motor paralysis of the extraocular muscles. With this work I have collected a series of cases in which the intraocular pressure was measured on the operating table before the retrobulbar injection and five minutes after it. These cases and some others form the basis of this preliminary report. It is hoped that this report will stimulate the interest of others to study this problem, since it is an important part of the physiology of the eye that has received very little attention. I would like to say that this is by no means a controlled experimental study, but simply a review of clinical findings and an attempt to evaluate these findings in the light of our present knowledge.

The technique of the orbital injection varied slightly but in general 2 cc. of 2-percent novocain containing adrenalin 1:1,000 was injected deep into the orbit, using a 5-cm., No.-25 needle. In some cases 4-percent novocain was used and the exact amount of adrenalin was not measured carefully except in the later cases in which 0.4 cc. to the ounce was used. The patients all had some basal anesthesia, sodium ortal or morphine and scopolamine. Also 4-percent and 10-percent cocaine with pilocarpine (1 percent) and adrenalin drops were instilled in the conjunctival sac, starting 20 minutes preoperatively. The facial nerve was blocked as completely as possible, using both the O'Brien[17] and Van Lint[18] methods. In many cases the Klein[19] technique was also added.

The tension was taken with the Schiøtz tonometer (sterilized in zephiran (1:1,000) just before the retrobulbar injection and the second tension five minutes later. If the orbital injection is properly placed deep in

the base of the orbit, the motor block comes on almost at once and the patient is unable to move the eye in any direction when asked to look-up or down, right or left. This effect was graded on a percentage basis, counting 20 percent off for each rectus still functioning and 10 percent for each oblique still active. For example, if the eye rotated only laterally, the motor block was considered to be 80 percent perfect. If two muscles were still active, the block was considered to be 60 percent effective. If movement was good in all directions but one, the motor block was listed as only 20 percent. There were also slight gradations for partial functions.

In the cataract operations, it was possible to set up a standard for posterior segment pressure—or vitreous pressure, as I have called it. When the eye is opened with a Graefe knife, the lens and iris diaphragm moves forward in the majority of cases, just filling the anterior chamber. This was recorded *as normal vitreous pressure.* If this movement forward was sufficient to cause gaping of the wound, a prolapse of the iris, or a horizontal wrinkle in the cornea, this was considered to be evidence of *positive vitreous pressure.* If the cornea collapsed or if the iris diaphragm did not move forward to fill the anterior chamber and an air bubble filled the chamber spontaneously, this was considered to be evidence of *negative vitreous pressure.*

Before looking at the clinical findings, it will make things more understandable if we review our knowledge of what takes place when novocain and adrenalin are injected behind the globe. The depth of the injection, of course, has some effects on the results. The novocain when injected deeply blocks the motor nerves, which relaxes the extraocular muscles more or less completely. The novocain also blocks the sensory nerves entering the base of the orbit, chiefly the nasociliary branch of the trigeminal. This produces anesthesia of the entire globe with anesthesia of the conjunctiva surrounding the cornea. It should block *both* the sympathetic and parasympathetic activity coming to or from the ciliary ganglion. The pupil dilates with a simple paralysis of the third nerve, but in my cases the pupil remained small because the iris was under the influence of cocaine and pilocarpine. I do not know what happens to the ciliary muscle. I hope that Dr. Harold G. Scheie will be able to tell us. The anterior chamber, however, becomes noticeably deeper in most cases. Is this effect due to relaxing the tone of the ciliary muscle? What happens to the vessels in the choroid? Do they dilate or constrict? A definite correlation between deepening of the anterior chamber and drop in tension has not yet been made.

The novocain placed this far back in the orbit should also block the optic nerve but for some reason this does not take place. Perhaps the optic-nerve sheath protects the nerve. I have checked the vision in most of these cases and have found the optic nerve to be as fully active as the state of the eye would permit. That is, in the aphakic cases these patients could count fingers promptly and accurately at the close of the operation and there was no gross field defect.

It has been generally accepted that the adrenalin placed in with the novocain is the drug that produces the lowering of the tension. Dr. Walter Atkinson believes that the adrenalin produces its effect by constricting the small arteries entering the globe but not affecting the venae vorticosae, which are more forward. I will present some findings later which indicate that the answer to the effect of the adrenalin is not this easy. To my surprise, I found that the effect of the adrenalin was relatively small and I am still in doubt as to just where the effect takes place.

This present study is based on 65 cataract operations and 40 glaucoma operations which had complete records of the tension before and five minutes after a deep orbital injection. Also the amount of motor block and the vitreous pressure after the globe was opened were recorded. There should be some rela-

tionship between the percentage of lowering of the ocular tension, the percentage of motor block, and the state of the vitreous pressure. The age of the patient may be an important factor, since this influences the rigidity of the sclera and the expansibility or contractability of the vascular bed. The vitreous body also changes with age, tending to become more fluid and perhaps chang-

There were wide variations ranging from 60 percent to no drop at all. The chart also shows that, along with the rise in initial tension, the base pressure goes up, starting at 10 and increasing to 15 mm. Hg. This will be considered later when discussing the 40 cases of glaucoma.

In the cataract series there were 34 males with an average lowering of tension of 31.9
Chart 1 (Gifford). The percentage of lowering of the tension increases only slightly with an increase in the initial tension.

ing in other properties as well. It is obvious from looking at these variable factors that the problem is not a simple one.

It was noticed immediately that the actual amount of drop in tension depends on the initial level of the intraocular pressure and that the percentage of lowering of tension would give a better figure to use for this study. The amount of drop in tension was therefore changed to percentage of lowering of the tension. From Chart 1, it is seen that the percentage of lowering of the tension increases only slightly with an increase in the initial tension. The average percentage of lowering for the cataract series was 33.

percent and 31 females with an average lowering of 36 percent. This slight difference is probably not significant and would indicate that sex difference does not play a part in the tension-lowering mechanism.

The age of the patient did not influence the percentage of motor block. The average age of the 34 cases with more than 65 percent motor block was 65.9 years. For the 31 cases with less than 65 percent motor block the average age was 65.2 years. However, age seems to have some correlation with the state of the vitreous (Chart 2).

The average age for the cases with negative pressure was 69 years. The average of

the cases with normal vitreous pressure was 65 years, while the average of cases with positive vitreous pressure was 61 years.

was 37 percent. The average age for the entire group was 66 years. This is a relatively old group in which sclerotic vascular
Chart 2 (Gifford). Age seems to have some correlation with the state of the vitreous.
Chart 3 (Gifford). Effect of motor block on ocular tension and vitreous pressure.

The age of the patient does not seem to have a great effect on the percentage of lowering of tension.

The older and younger groups had slightly less fall—29 percent and 30 percent respectively—than the middle age group, which

changes are present. If a really young group were checked, they might show more difference or they might show a similar percentage of lowering due to the compensating effect of a more elastic sclera.

Chart 3 also shows the effect of the per-

centage of motor block on the percentage of lowering of tension.

Eleven cases with 100-percent motor block had an average lowering of tension of 34.6 percent, 12 cases with 60 percent motor block an average of 31 percent and 8 cases with 20 percent or less motor block showed only 25 percent.

The bottom part of Chart 3 shows that the percentage lowering of tension has only

when the percentage of motor block is poor the percentage of tension lowering is less (28). This would indicate that the extraocular muscles play a part in maintaining normal ocular tension and when they are relaxed by the orbital injection the percentage of lowering is greater. This chart also shows the effect of the motor block on the vitreous pressure. There were only two cases of positive pressure when the motor block was bet-
Chart 4 (Gifford). Correlation of the percentage of motor block with the percentage of tension lowering and the state of the vitreous pressure.

a little correlation with the negative and normal vitreous pressure, the average percentage of lowering being 37.6 and 36.6 respectively. The positive vitreous cases showed a percentage lowering of 19.9. This would indicate some correlation with positive vitreous pressure.

In attempting to explain the mechanism of the fall in intraocular pressure, the percentage of motor block was correlated with the percentage of tension lowering and the state of the vitreous pressure.

Chart 4 shows that as the percentage of motor block increases, the percentage of tension lowering increases (37.1), and also

ter than 65 percent. There were seven cases when it was less than 65 percent.

The effect of the motor block on the vitreous pressure and the percentage lowering of tension are shown graphically in Chart 5.

When the motor block was good there were more cases with negative pressure. The effect of the muscle tone was larger in this direction. When the percentage of lowering of tension was poor there were more cases of positive vitreous pressure. This is not an absolute correlation. There is some other factor operating. This appears to be the age of the patient. The three factors—age, percentage of lowering of pressure, and the

Chart 6 (Gifford). Percent of lowering tension grouped according to initial tension in a study of 40 glaucoma cases.

amount of motor block—all affect the vitreous pressure and in any individual case all three must operate in the same direction to be sure of producing either negative or positive vitreous pressure. Any one factor may overshadow the effect of the other. This was shown to be true in several individual cases. A patient, aged 73 years, with a small percentage drop, 15, had a negative vitreous pressure but a 90-percent motor block. The patient with the lowest initial pressure, 10

due to a continued rise in the base pressure. The rise in the base pressure is shown very clearly. It seems to me that this is the same base pressure brought out by Dr. A. B. Reese in his paper read before this society last year.

If this proves to be the case, an orbital injection would provide a quick and simple method for determining this base pressure. This would eliminate the "long-range perspective" that Dr. Reese feels is so desirable

mm. Hg, had only a 20-percent drop and only 60-percent motor block, but negative vitreous pressure. He was 88 years of age. In this case, age was a deciding factor. For practical purposes in cataract surgery, youth, a low percentage of tension lowering, and poor motor block will tend to produce positive vitreous pressure. But if any of these three factors can be changed sufficiently, normal or negative pressure may be the result. Conversely, old age, a good motor block and a large percentage of fall will produce negative vitreous pressure, but if one of these is missing positive vitreous pressure may result.

The 40 glaucoma cases are shown on Chart 6. These are grouped according to the initial preinjection tension.

Like the cataract series, there is a tendency for the percentage of lowering of tension to be greater with a higher initial tension, but the average percentage of lowering was slightly less, being 29. This must be

to determine the choice of operation for each individual patient. A high base pressure would indicate a trephination or Lagrange sclerectomy. The oribtal injection might also prove to be a useful provocative test in preglaucoma patients. It will take considerably more study to set up normal percentage-lowering curves but I am sure such curves would be invaluable in understanding and treating glaucoma.

How does the orbital injection produce its tension-lowering effect? I have shown that relaxing the extraocular muscles has some influence on reducing the tension.

The adrenalin which has generally been given the credit for the tension-lowering effect, surprisingly, does not seem to be necessary (table 1).

Table 1 shows that it is possible to produce a slightly greater than average percentage of lowering of tension without any adrenalin in the orbital injection. The average for five cases was 35.6 percent. Saline

alone will not cause a lowering of the ocular tension but adrenalin alone has some effect.

Saline and adrenalin were injected the day before operation and the tension checked alone in the second, and about the same amount in the third. More of these cases will have to be done before the effect of adrenalin alone can be evaluated precisely.
Chart 7 (Gifford). Tension curves produced by deep orbital injection.

(broken line). At the time of operation, the same amount of adrenalin was added to the novocain and the tension again checked (solid line). See Chart 7.

The effect of the adrenalin alone was not as great as when it was combined with novocain in the first case. There was slightly more lowering of tension with the adrenalin

A similar tension-lowering effect can be produced by sodium pentothal anesthesia (table 2).

This would indicate that there is a higher center in the brain for control of ocular tension. Since the amount of the effect is about the same as when an orbital injection is used, it would indicate that they both act

produce its tension-lowering effect by block-
ing the parasympathetic activity of the third
nerve and the ciliary ganglion. How this
effect is produced is unknown. At present
this is not much more than a working hypo-
thesis but it seems to apply to the normal
eye at least.

base pressure has become elevated.

In acute glaucoma, however, there were
some exceptions (table 3).

There were three cases where no reduction
of tension occurred. These eyes had lost
their tension-lowering capacity. It seems that
the base pressure had simply become ele-

vated to a point equal to the initial pressure.

The tension was checked during and after enucleation in several cases (table 4).

Table 4 shows that the eyes with a high base pressure actually maintain some or all of this pressure after the eye has been removed from all nervous and circulatory control. It demonstrates that there may be an actual anatomic change in these eyes that is producing the elevation of the base pressure.

Some eyes failed to show any response to orbital injection, although the initial pressure was low. These eyes were not glaucomatous (table 5).

Table 5 shows four cases that did not show any drop in tension when the initial pressure was low. One eye had had a severe iritis but in the others the lack of drop in tension could be explained only on the basis of a poor motor block or some specific anatomic change that produces an eye that has no tension-lowering potential.

CONCLUSIONS

This study would indicate that in the normal eye there is a dynamic factor controlled by the nervous system that produces a certain amount of the ocular tension. This seems to be a relatively constant factor amounting to about 33 percent of the initial ocular tension. This dynamic factor is influenced by the tonus of the extraocular muscles and the parasympathetic activity of the third nerve. It can be separated from the total ocular tension by an orbital injection of 2-percent novocain, adrenalin, or sodium-pentothal anesthesia. This leaves a residual or base pressure that shows a tendency to increase slightly in the normal eye as the intraocular pressure rises. This base pressure is maintained by still-unknown factors but must in some way be associated with the hydrostatic pressure of the blood and the elasticity of the sclera.

This study would indicate that, in the glaucomatous eye, the base pressure has become elevated, in some eyes to such a degree that there is produced an anatomic change that resists all tension-lowering devices, such as drops, orbital injection, cutting the recti muscles, and even enucleation.

I feel certain that further clinical study and basic research on the choroid and its association with the ciliary body is necessary before the glaucoma problem can be solved. I know certainly that the percentage of vitreous loss in cataract surgery can be greatly reduced by using a deep orbital injection that produces a motor block of the extraocular muscles as well as more complete anesthesia, and a lowering of the intraocular pressure.

CHOICE OF A MIOTIC AGENT FOLLOWING RETROBULBAR ANESTHESIA*

HAROLD G. SCHEIE, M.D., AND GAYLORD OJERS,† M.D.

Philadelphia, Pennsylvania

INTRODUCTION

For some years it has been the custom in the Department of Ophthalmology at the Hospital of the University of Pennsylvania to instill physostigmine as a prophylactic measure against iris prolapse following delivery of the lens from eyes in which intact pupils have been preserved. Because an occasional prolapse continued to occur in spite of this and other precautions, the pupils of several eyes were examined at various intervals during the first 24 hours after extraction.

A significant number of pupils, in eyes which had received retrobulbar and subconjunctival injections of procaine hydrochloride, were found to have remained dilated for several hours after operation. This persistent mydriasis was surprising in view not only of the instillation of physostigmine but also of the added factor of trauma during operation. The pupils had been dilated preoperatively by homatropine hydrobromide.

In searching for a possible explanation, the phenomena described in the denervated pupil by Anderson[1] in 1905 was recalled. He found that, following removal of the ciliary ganglion from cats, the pupils on the operated side dilated widely. He demonstrated that with complete denervation, following such removal, physostigmine was ineffective in constricting the pupil. Furthermore, the pupil constricted normally or more actively than normal to pilocarpine solution.

Loewi, Dale, and other workers[2] subsequently explained these phenomena when they evolved the neurohumoral theory of transmission of nerve impulses. In part, this theory postulates that a nerve impulse stimulates an organ to its physiologic action by a chemical substance called the effector substance. This is liberated by the terminal nerve fiber upon the arrival at that point of the nerve impulse. The effector substance liberated by the nerve endings of the parasympathetic nervous system, which include those supplying the sphincter iridis, is acetylcholine. Stimulation of a muscle cell to contraction involves a special apparatus called the myoneural junction, which consists of the terminal nerve fiber and the muscle cell which has a specialized area called the motor end-plate. Acetylcholine, liberated by the nerve ending, has a special affinity for the motor end-plate and through it stimulates the muscle cell to contraction. Relaxation of the muscle cell is brought about by cholinesterase, constantly present in the tissues, which rapidly destroys the acetylcholine.

The various miotic agents in common use clinically depend for their effect upon their ability to intervene in the myonueral junction in various ways. Pilocarpine produces miosis by mimicking the action of acetylcholine. Physostigmine, on the other hand, stimulates the sphincter muscle only indirectly. It inhibits or inactivates cholinesterase, thereby preventing the destruction of acetylcholine which now accumulates in concentrations sufficient to give continuous stimulation of the sphincter iridis with resulting miosis. Physostigmine, therefore, must have acetylcholine available to be effective, and acetylcholine is produced only by intact nerve endings. The removal of the ciliary ganglion or destruction of the ciliary nerves peripheral to this ganglion destroys the source of acetylcholine in the sphincter iridis. This renders physostigmine ineffective and explains its failure to constrict the pupils of the cats used in Anderson's ex-

periments. On the other hand pilocarpine, which acts directly, as does acetylcholine, continues to be effective even after complete denervation.

It occurred to us that such a situation might account for the persistent mydriasis often seen in our patients following cataract extraction. A temporary postganglionic denervation of the sphincter pupillae might have resulted from the retrobulbar injection of procaine hydrochloride. This would of course render physostigmine ineffective when instilled postoperatively. The following experiments were therefore undertaken.

OUTLINE OF EXPERIMENTS

1. Observation of the effect of the retrobulbar injection of procaine hydrochloride upon the size and reaction of the normal pupil.

2. The effect of retrobulbar injections of procaine hydrochloride upon the pupillary response to miotic agents.

3. The effect of retrobulbar injection of procaine hydrochloride upon pupils previously rendered miotic by instillations of physostigmine or pilocarpine.

4. A comparison of the miotic effect of physostigmine and pilocarpine in overcoming homatropine and paredrine.

5. Determination of the most effective miotic agent for pupils previously dilated by retrobulbar injections of procaine hydrochloride and instilled homatropine or paredrine to simulate the clinical conditions encountered during cataract extraction under local anesthesia with retrobulbar procaine hydrochloride.

METHODS OF EXPERIMENTS

Unless otherwise stated, all experiments were carried out upon dogs anesthetized with nembutal. Ten eyes were used for each experiment. The term retrobulbar injection refers throughout to the injection of 2 cc. of 4-percent procaine hydrochloride. This was accomplished by rotating the eye upward with a fixation forceps and inserting

the needle through the lower eyelid. If the retrobulbar injection was to be repeated, the syringe was detached and the needle left in place between injections. The miotic agents used were physostigmine (0.5 percent), and pilocarpine (1 percent and 10 percent), and one tenth of 1-percent di-isopropyl fluorophosphate. To insure adequate administration they were instilled twice, five minutes apart. All pupillary measurements were estimated by the use of a millimeter ruler. Figures given represent the average for the 10 eyes. Pupils were arbitrarily said to be miotic when 3 mm. or less in diameter.

EXPERIMENTAL DATA

Effect of retrobulbar injection of procaine hydrochloride on the normal pupil.

The pupils of nearly all animals dilated widely within 30 to 60 seconds after retrobulbar injection. Occasional failure to dilate was due to a poorly placed injection, since a second injection with the needle properly inserted resulted in prompt mydriasis. The pupils were fixed to light. The mydriasis was found to persist for an average time of 160 minutes after retrobulbar injection.

Effectiveness of pilocarpine and physostigmine following retrobulbar procaine injection.

1. The effect of retrobulbar injection of procaine hydrochloride upon pupillary response to miotics:

The miotic effect of physostigmine, pilocarpine, di-isopropyl fluorophosphate (D.F.P.) on pupils rendered mydriatic by retrobulbar injection was tested.

Pilocarpine (1 percent) was found to constrict the pupils to 3 mm. in an average time of 24 minutes, while pilocarpine (10 percent) had a similar effect in 20 minutes (chart 1). This time interval was shorter than that found in the normal eye of unanesthetized dogs not subjected to retrobulbar injection. The effect of physostigmine (0.5 percent) on the other hand, was markedly delayed (chart 1). Miosis oc-

curred, but only after a time interval of 80 minutes as compared with 40 minutes in the normal control animals. D.F.P. also produced miosis, but like physostigmine only after a significant delay, which averaged 120 minutes.

Physostigmine and D.F.P. therefore both

10 percent), and a retrobulbar injection was given. No dilatation of the pupil ensued. Similar experiments were done with pupils constricted by physostigmine or D.F.P. The physostigmine-treated pupils dilated almost immediately following the retrobulbar injection of procaine, while 9 of the 10 pupils
Chart 1 (Scheie and Ojers). Time required by pilocarpine and physostigmine to produce miosis in dog eyes with pupils dilated by retrobulbar injections of procaine hydrochloride.

became effective only after the effect of the retrobulbar injection began to wear off, a time previously found to be approximately 50 to 60 minutes following the injection.

After this interval, the pupils treated with physostigmine rapidly constricted. They became miotic twice as rapidly as the control eye which had had only a retrobulbar injection. These findings were compatible with those of Anderson and other workers with denervated sphincter muscle, and they indicated that a temporary ciliary ganglionectomy had been accomplished by the retrobulbar injection of procaine.

constricted by D.F.P. dilated following retrobulbar injection. There was more of a lag as indicated by a time range of 1 to 8 minutes.

3. Clinical observations on the pupil following retrobulbar injections of procaine hydrochloride:

Some of the experiments just described in dogs were repeated upon patients who were being operated upon under local anesthesia, and the results were found to be similar. No drops except pontocaine hydrochloride (1 percent) were instilled locally. Retrobulbar injections were made contain-
Chart 2 (Scheie and Ojers). Time required by pilocarpine and physostigmine to produce miosis in human eyes with pupils previously dilated by (A) paredrine and (B) homatropine.

2. Effect of retrobulbar injection of procaine hydrochloride on pupils previously constricted by pilocarpine, physostigmine, or D.F.P.:

Miosis was produced in dog eyes by the instillation of pilocarpine (1 percent or

ing 4-percent procaine hydrochloride. Adrenalin was not used either by instillation or injection. Several patients who were being operated upon for strabismus were given bilateral retrobulbar injections. Pupil dilatation was maximal in 40 to 50 seconds (figs.)
Fig. 1 (Scheie and Ojers). Photographs showing dilatation of pupils following retrobulbar injection of procaine hydrochloride and subsequent ineffectiveness of physostigmine. (A) Pupils prior to retrobulbar injection. (B) Mydriasis immediately following retrobulbar injection of procaine hydrochloride. (C) Pupils 15 minutes later, following instillation of physostigmine in the right eye and pilocarpine in the left eye. (D) Pupils 25 minutes later showing marked miosis from pilocarpine.

1A and 1B). Physostigmine (0.5 percent) was then instilled in one eye and pilocarpine (1 percent) in the other. Pilocarpine caused miosis which began in 5 minutes and was nearly complete in 20 minutes (figs. 1C and 1D). The pupils of several patients were then made miotic by instillations of physostigmine or pilocarpine prior to retrobulbar injections. Miosis was found to persist in the pupils constricted with pilocarpine, but those constricted by physostigmine promptly dilated.

Effectiveness of pilocarpine and physostigmine in constricting pupils previously dilated by homatropine or paredrine.

1. Pupils of 10 human eyes were dilated by two instillations of 1-percent paredrine five minutes apart. One-percent pilocarpine and 0.5-percent physostigmine were found to produce miosis with nearly equal rapidity (chart 2-A). Miosis of 3 mm. or less occurred within approximately 20 minutes.

2. Pupils of 12 human eyes were dilated by two instillations of homatropine (2 percent), five minutes apart. One-percent pilocarpine was then instilled and found to be quite ineffective in producing miosis. By the end of four hours, less than 1 mm. of contraction had occurred (chart 2-B). One-

Effectiveness of pilocarpine on pupils dilated by retrobulbar injections of procaine hydrochloride and the instillation of either homatropine or paredrine.

Having determined that pilocarpine, in contrast to eserine, produced prompt miosis in pupils dilated by retrobulbar injections, it seemed to be the miotic agent of choice following cataract extraction. However, because pilocarpine was relatively ineffective in counteracting homatropine dilatation, it was felt that paredrine would be the better agent for preoperative mydriasis whenever retrobulbar anesthesia was contemplated. The following experiments were performed to observe the effectiveness of pilocarpine in overcoming mydriasis produced by a combination of retrobulbar injection and homatropine or paredrine.

1. Because pupil dilatation was used as the criterion of a successful block, it was necessary to give the retrobulbar injection before instilling homatropine or paredrine. The needle was left in place as previously described to be sure subsequent injections were also properly placed. For some reason dog irides seemed refractory to homatropine and particularly to paredrine. Twelve instillations of one drop of 1-percent paredrine
Chart 3 (Scheie and Ojers). Time required by pilocarpine (1 percent and 10 percent) to produce miosis in dog eyes with pupils previously dilated by retrobulbar injection of procaine hydrochloride and (A) paredrine or (B) homatropine to simulate clinical conditions during cataract extraction.

half-percent physostigmine, on the other hand, produced a miosis of 3 mm. in 12 human eyes after an average interval of about 70 minutes (chart 2-B).

were instilled into each eye at 5-minute intervals to be certain that the mydriatic would be absorbed. Two hours from the initial drop, a second retrobulbar injection was

made through the previously placed needles, and pilocarpine (either 1 percent or 10 percent) was instilled twice at 5-minute intervals. Miosis resulted in an average time of 70 and 75 minutes for each strength solution respectively (chart 3-A).

2. Using the same routine, six drops of homatropine (2 percent) were substituted for the paredrine in another series of dog eyes. In these experiments 1-percent and 10-percent pilocarpine were equally ineffective in that no significant miosis had resulted with either strength solution at the end of 310 minutes (chart 3-B). The eyes were not observed further.

DISCUSSION

Preliminary experiments with dog eyes showed that retrobulbar injections of procaine hydrochloride produced prompt pupillary dilatation of the ipsilateral eye. The pupil was fixed to light. These pupils responded to pilocarpine and eserine in a manner identical to that described by Anderson in animals from which the ciliary ganglion had been removed.

Prompt miosis was produced by the instillation of pilocarpine, but physostigmine was ineffective. Di-isopropyl fluorophosphate, which has physiologic properties similar to physostigmine, was likewise ineffective. The normal pupillary response of these drugs was regained after an average time of about 80 minutes at which time the effect of the retrobulbar injection of procaine had begun to wear off. Continued retrobulbar injection of procaine could prolong the mydriasis indefinitely.

Anderson in his experiments, however, found that physostigmine did not become ineffective for at least 24 hours after ciliary ganglionectomy; whereas, in our experiments with procaine this occurred within a period of seconds following the retrobulbar injection.

The explanation is obscure, but it seems likely that in Anderson's experiments the irritation of the severed nerves might have resulted in continued production of acetylcholine at the nerve endings. In the experiments with procaine, depression rather than irritation of the nerve fibers seemed likely. Acetylcholine was, therefore, no longer formed and physostigmine immediately became ineffective.

Experiments upon patients who were being operated upon under local anesthesia for strabismus gave similar results. Retrobulbar injections of procaine promptly produced mydriasis. Physostigmine was ineffective in producing miosis and remained so for 3 to 5 hours, but pilocarpine constricted these pupils normally. These experiments suggest that, in the presence of retrobulbar anesthesia, physostigmine is probably not the miotic agent of choice following cataract extraction.

Many surgeons believe the majority of iris prolapses occur during the first few hours after cataract extraction. During this immediate postoperative period the wound edges are very loosely coaptated and the anterior chamber probably forms and empties several times; meanwhile the aqueous tends to force the iris through the wound. Prompt postoperative miosis with retraction of the iris from the wound is therefore desirable, and from these experiments pilocarpine would seem to be the agent of choice.

Another factor which greatly influences the rapidity of postoperative miosis is the preoperative mydriatic agent employed. It is well known that the preoperative accidental instillation of atropine predisposes to iris prolapse because neither the trauma of operation nor miotics promptly constricts such pupils. For this reason homatropine and paredrine are the most commonly used preoperative mydriatics. We, therefore, tested the effectiveness of physostigmine and pilocarpine in counteracting homatropine and paredrine.

Pilocarpine was found to be quite ineffective in overcoming homatropine. Miosis had not occurred at the end of three hours.

Physostigmine produced miosis in such pupils in an average of 1¼ hours. On the other hand, these miotics were equally effective in overcoming mydriasis produced by paredrine. Such pupils were constricted within approximately 20 minutes by either substance. Because pilocarpine seemed to be the miotic of choice following retrobulbar anesthesia, we tested its effect following dilatation produced by combinations of retrobulbar injections of procaine and instillations of homatropine or paredrine. Prompt constriction of the pupils dilated by retrobulbar injection and paredrine occurred, whereas constriction occurred only after five hours when homatropine had been used. These findings would suggest paredrine should be employed rather than homatropine for preoperative mydriasis.

A miotic pupil is desirable throughout the corneoscleral trephining operation for glaucoma because it facilitates the performance of a peripheral iridectomy with the maintenance of an intact sphincter muscle. Experiments demonstrated that pupils constricted by pilocarpine remained undilated following the retrobulbar injection of procaine while those constricted by eserine dilated rapidly. Thus pilocarpine should be used preoperatively before a trephining operation, if miosis is to be maintained throughout the procedure when retrobulbar anesthesia is employed.

Retrobulbar injection of procaine hydrochloride, as suggested by Icaza[3] in 1946, has been employed in the treatment of acute congestive glaucoma. In view of the experiments just described, pilocarpine or some substance which acts similarly upon the myoneural junction should be used prior to the injection to avoid pupillary dilatation. Failure to do so, or the use of eserine alone, would result in wide mydriasis and possible aggravation of the glaucomatous state by further narrowing of the angle of the anterior chamber.

CONCLUSIONS

1. Retrobulbar injection of procaine temporarily produces an effect identical to the removal of the ciliary ganglion. The pupil is dilated and fixed and fails to constrict to eserine but does so promptly to pilocarpine.

2. Evidence therefore suggests that, if a miotic is to be employed following cataract extraction done under retrobulbar anesthesia, pilocarpine is preferable to eserine because eserine is rendered ineffective by the injection.

3. Paredrine is theoretically a more ideal preoperative mydriatic agent than homatropine because it is much more readily counteracted by pilocarpine. Although ordinarily a weak mydriatic, the retrobulbar injection of procaine adds to its effectiveness through paralysis of the sphincter pupillae.

4. If mydriasis is to be prevented following retrobulbar injection of procaine, particularly as used in the treatment of acute congestive glaucoma, pilocarpine should be used beforehand.

DEGREES OF CORRECTION PER MILLIMETER OF SURGERY*

RICHARD G. SCOBEE, M.D.
Saint Louis, Missouri

The title of this paper suggests little of interest for the orthoptic technician. It is the ophthalmic surgeon who should be interested in such a discussion. Unfortunately, many an orthoptist has been forced against her will into the position not only of saying when surgery should be done on a patient with heterotropia but also what operation should be done.

The blame for such a lamentable situation, when it exists and it is unhappily all too common, lies entirely with the surgeon. The oculist that is too lazy to delve into the intricacies of dysfunctions of the oculorotary muscles has no business attempting the surgical correction of such cases. There are many surgeons, however, who do exactly that.

A patient with crossed eyes will enter their consulting room. Their first step after refraction is to refer the patient to an orthoptist and then sit back and wait. The orthoptist will refer the patient back to the ophthalmologist's office at intervals during orthoptic training but nothing happens. It finally becomes obvious that the surgeon is going to do nothing until he is forced into it and the conscientious orthoptist will, therefore, usually suggest surgery when it is indicated. The surgeon usually agrees with surprising alacrity and will ask in an off-hand manner for the orthoptist's opinion as to what should be done.

Make no mistake about this seemingly casual question for it is more frequently than not asked in dead earnest. Any suggestion that the orthoptist makes is usually followed to the letter. If the results are not good, the surgeon then blames the orthoptist rather than himself. If the results are good, he considers it a clever bit of surgery and often forgets the source of the advice. Actually, he has only himself to blame and he has taken an unfair advantage of the orthoptic technician and placed her in a very embarrassing position.

DIAGNOSTIC DIFFICULTIES

Every ophthalmologist who does surgery is confronted with one or more patients with heterotropia early in his career of private practice. Diagnostic procedures which seemed quite reliable during a residency quickly assume an alarming air of uncertainty in private practice when the responsibility for the case is his and his alone.

It is a simple matter to measure the number of degrees in the deviation of a patient with heterotropia. The problem is what to do once the amount of the deviation is known. It is an established fact that there are 360 degrees in a circle and that the circumference of the adult eyeball is in the neighborhood of 72 mm. If one divides 360 by 72, it will be found that each millimeter represents five degrees. The mathematical principle here is sound. However, the surgeon who expects to obtain 5 degrees of correction per mm. of surgery is doomed to many disappointments in dealing with the oculorotary muscles.

The young surgeon begins a search of the literature for some indication of exactly how much surgery to do when the heterotropia amounts to so-and-so many degrees. He will find some paper published on the subject with no great difficulty and will apply the figures given therein to his own case or cases. The results will be sometimes

gratifying but more often bewildering and bitterly disappointing.

After one or two such unfortunate occurrences, he will begin to search the literature anew until he finds another paper on the subject. Here again, some authority is saying that for so many millimeters of recession he usually obtains so-and-so many degrees of correction. The young surgeon applies these new and, we might add, different figures to subsequent cases but again the results will be confusing.

The surgeon finally concludes that no one knows a great deal about the subject and consequently that he knows as much as anyone. His technique in dealing with patients with heterotropia is from that time onward a trial-and-error one and is far from satisfactory.

AVERAGES MISLEADING

There is one basic fallacy in all papers which report on "degrees of correction per millimeter of surgery" and it is that the figures given are always *averages*. Such averages can be, and usually are, highly deceptive.

A good analogy may perhaps be found in a survey, let us say, of wages in various small industries. One industry may employ 20 persons whose salaries range from $100 to $300 per month; the *average* wage in this industry might be $200 per month. Another industry, also employing 20 persons, might have two high-powered publicity men with salaries of $1,600 per month while the rest of the employees get no more than $150 per month; the *average* wage in our second example might be $260 per month.

The conclusion implied by a knowledge of only the average wage figure per month with respect to the actual incomes of the individual workers in the two industries is obviously false. In exactly the same way, average figures for the results of muscle surgery are prone to be deceptive.

No TWO CASES ALIKE

It is extremely rare to find two patients with heterotropia whose conditions are identical, and yet innumerable patients can be found who have, let us say, 30 degrees of esotropia. The point to be recognized and emphasized is this: the 30 degrees of deviation is not particularly important; much more important is *why* the 30 degrees of deviation are present.

About the only thing that any two patients, both having 30 degrees of esotropia, share in common is the degree of their deviation and even that may vary from time to time. From an intimate knowledge of only one of these cases, we can say little or nothing about the other. A lizard and an elephant have little in common except that they are both vertebrates. An intimate acquaintance with a lizard does not enable us to say anything intelligent about the elephant unless we have also seen and studied the elephant.

Admittedly there is nothing new nor particularly startling in the foregoing considerations. The mere realization that there is much variation between two patients with identical amounts of heterotropia is small consolation to the surgeon who is faced with the necessity of correcting the deviation surgically.

CONSIDERATIONS IN PLANNING SURGERY

There are a number of points to be taken into consideration in planning surgery in the patient with crossed eyes and no one of them alone yields sufficient information to enable an accurate decision to be reached. Let us review these considerations briefly.

1. Age. How old is the patient? The same operation on a child will usually result in far more correction than on an adult.

2. Duration. How long has the tropia been present? The same operation will produce more correction on a tropia which has been present for a short time than on one that has been present for a number of years.

3. How variable is the deviation? The patient whose tropia measures 10 degrees on one visit, 30 degrees on another visit, and 20 degrees on a third visit will show far more correction from the same operation than will a patient whose tropia measures 30 degrees on every visit.

4. Do glasses reduce the deviation? The same operation will produce more correction in a patient whose tropia is reduced by glasses, that is, in which there is an accommodative element, than in one whose tropia is affected not at all by glasses.

5. How large is the deviation? The same operation will produce more correction in a patient whose tropia measures 45 degrees than one whose tropia measures only 25 degrees.

6. Is there obvious paresis? A patient whose tropia is the result of a mild paresis combined perhaps, with other factors will show more correction following the same operation than will a patient whose deviation is solely the result of a severe paresis.

7. What is the near point of convergence? If the convergence near point is poor, that is, remote, in a patient with tropia, secondary convergence palsy is present. The immediate postoperative effect of a recession of the medial rectus muscle is much less in a patient with secondary convergence palsy than in one with no such palsy.

8. What degree of fusion is present? Even small amounts of second-degree fusion will appear to increase materially the correction effected by an operation in the patient with heterotropia. This is true for obvious reasons.

9. Which are the offending muscles? There is no substitute for an accurate identification of the muscle or muscles involved in the patient with heterotropia. One will occasionally hear a surgeon remark that ". . . it makes no difference which eye one selects for surgery in heterotropia because the two eyes are conjugated and work as a team." Actually, nothing could be farther from the truth. Surgical attack on the correct muscle will give far more correction than the same operation performed on an improper muscle.

10. Which is the dominant eye? The deviation which is present with the dominant eye fixing is the deviation at whose correction the surgeon must aim. This is true whether it be primary or secondary deviation, although it is imperative that the type of deviation be known. The same operation will go much farther toward correcting secondary than primary deviation.

11. Is the tropia monocular or alternating? The same operation will usually result in greater correction in the patient with monocular heterotropia than in one with an alternating type of deviation.

12. Is the tropia constant or intermittent? The same operation will have a greater effect in an intermittent heterotropia than in a constant one.

PROBLEMS AT OPERATION

The points so far enumerated can be determined as easily by the orthoptist as by the surgeon. If these were all that mattered, the orthoptist would be perfectly competent to make detailed suggestions about the surgery to be performed in the patient with heterotropia. There are other factors to be considered, however—factors which can be properly evaluated only in the operating room. Let us consider them.

1. Effect of general anesthesia on the deviation. What happens to the deviation under general anesthesia? A patient whose esotropia disappears almost entirely or entirely under general anesthesia will show far more correction from the same operation than will a patient whose deviation is changed little if at all under the same circumstances. It should be stated here that the general anesthesia must be deep before the position of the eyes is evaluated; under shallow general anesthesia, esotropia often appears exaggerated while exotropia often seems to decrease in amount.

2. *What are the results of the forced duction test?* The forced duction test* may be used as an indicator, in the majority of cases, not of how much surgery to perform but of which muscles to attack. It should be obvious that the results of surgical attack on a primary offender will be greater than the same attack on a secondary offender. This point, which may seem vague, should be clarified in the next item for consideration. It does not refer to primary and secondary deviation.

3. *What anatomic anomalies are present?* The size, extent, and consequent significance of various anatomic anomalies found in connection with the oculorotary muscles in the patient with heterotropia should determine to a large extent the effect of surgery on these muscles. Anatomic anomalies frequently encountered are extra and thickened check ligaments, fused check ligaments, posterior check ligaments, foot-plate insertions, abnormal insertions, abnormal muscle slips, and abnormalities of the intermuscular membrane.*

4. *Elasticity of the muscle.* How elastic is the muscle which is being subjected to the surgical procedure? When severed from the globe, does it retract promptly into the orbit or does it retract slowly and incompletely? The greater the elasticity of a muscle, the greater the correction which will follow a recession of that muscle.

5. *Size of the muscle.* How large is the muscle? Recession of a large muscle will result in much more correction than recession of a small muscle for the same distance.

6. *Operative technique.* What is the technique of the surgeon? It might be thought that the operation of recession, for example, is a fairly well-standardized procedure. It is quite surprising, therefore, how many actual differences in technique may be found between two surgeons performing the same operation.

The surgeon who divides the check ligaments will get more correction than one who does not. The surgeon who severs the intermuscular membrane will get more correction than one who does not. The surgeon who finds and deals properly with anatomic anomalies will get more correction than one who does not. The surgeon who, inadvertently or not, strips the muscle of its sheath will get less correction than one who preserves it carefully intact. And yet both may be doing a recession operation.

Under the heading of operative technique should come the choice of the operation. Rather than attempting to perform many operations of different types and never performing any one procedure with a fair degree of skill, it is much wiser for the surgeon to practice one or two operations in order that he may master them. A perfectly suitable armamentarium is composed of one lengthening operation and one shortening operation. The recession and the resection will serve the average surgeon faithfully and well and neither is difficult.

7. *Postoperative care.* Immediate postoperative care in heterotropia is almost as important as is the operation itself. What might otherwise be a good result can be lost by lack of proper postoperative care. One is referring here to the use of atropine, glasses, orthoptics, or the prohibition of close work when any of these are indicated, either separately or in combination. The period of postoperative bandaging of the eyes is important with regard to the amount of correction to be obtained from the operation performed.

COMMENTS

It is obviously impossible for the orthoptist to evaluate any of the points listed in the second group for the very excellent reason that she is nowhere near the operating room. Such a decision must be made by the surgeon himself on the operating table. This point has been recognized by such leaders as Jameson, White, Kirby, and Prangen in the past 25 years.

---

* Scobee, R. G.: Anatomic factors in the etiology of heterotropia. Am. J. Ophth., 31:781, 1948.

It is surprising how many surgeons are prone to ignore this latter group of points. They concentrate on the first group of findings and preoperatively formulate a rigid plan of procedure for the operating table— a plan from which they refuse to deviate one iota, irrespective of the findings at operation.

The situation is similar to that of a man who decides to drive to a neighboring community by a certain one of several possible roads and insists on taking that road even though he is told that the bridge has been washed out at the last minute. He is, of course, riding for a fall and deserves no particular sympathy.

It is not at all unusual to obtain as much as 25 or occassionally even 30 *degrees*—not prism diopters—of correction from a recession of a single medial rectus muscle in the patient with esotropia, provided the operation is properly done. On the other hand, a recession operation on the same muscle, when improperly performed, may yield no more than 4 degrees of correction.

With all of the points mentioned for consideration, two facts should by now be obvious. The first is that *average* figures for "degrees of correction per millimeter of surgery" are worthless. The second is that no two cases of heterotropia are alike and each must be treated on the basis of its own individual pecularities if the treatment is to be rational and thus successful.

The orthoptist can and should be a tremendous help to the surgeon in considering the first group of points, but he must consider the second group alone. It is distinctly unfair to the orthoptist if the surgeon seeks to force her to make suggestions about surgery when she cannot possibly know all of the important factors concerned prior to the actual operation itself.

Diagnosis and some forms of nonsurgical therapy may well be within the province of the orthoptist in handling cases of dysfunction of the oculorotary muscles. Surgical therapy for such conditions is in the province of the ophthalmologist alone. The orthoptist will readily agree with the latter fact. It is the surgeon who must be occasionally reminded of it.

640 South Kingshighway (10).

DISCUSSION OF DR. SCOBEE'S PAPER

WENDELL L. HUGHES, M.D.
Hempstead, New York

Dr. Scobee kindly sent me a copy of this timely, important, and constructive paper prior to his presentation. A great many points have been emphasized. Anyone who has read any of his papers must realize the background of research behind the opinions expressed. His opinions are not a rehash of opinions he has read or heard others express. They are an honest attempt to get at and present the truth. Whether all of his conclusions will bear the test of time, only time will tell.

For those of you who are liable to feel that it is the place of the orthoptic technician to advise as to how much of a shortening or lengthening procedure should be done in any specific case, it is well to bear in mind that there are a great many variables in the technique of the surgical procedures.

In a resection for instance, should one measure the distance from the front of the clamp to the position of insertion of the sutures through the stretched muscle as it is pulled forward at the time of insertion of the sutures or should one measure the unstretched muscle? The latter is obviously the

theoretically accurate measurement but it is the usual custom to measure the distance on the stretched muscle.

With this in mind, it is obvious that one is taking out more muscle tissue in a case where there is little stretching than in a case in which the muscle is weak and thin and stretches a great deal and, therefore, more correction will result in the case of the more rigid muscle from the same recorded amount of excision.

1. Where the forceps are applied to the muscle is a factor. There is a variation of a couple of millimeters in the location of choice of various surgeons. The portion anterior to the forceps is usually omitted from calculations. This portion retracts to the clamp as soon as it is severed. Some men will leave a millimeter or two of the tendon at the stump still attached to the eye, others will cut the muscle very close to the insertion.

2. The manner in which the sutures are placed and their number may cause variations. If the sutures are placed through the muscle and then the section of muscle cut off before pulling up the sutures, as in the original Reese technique, there will be a certain amount of longitudinal slipping of the sutures in the muscle and the effect will be only about two thirds of the effect produced by holding the muscle forward by the clamp and tying the sutures before excising the muscle section. Whether or not the same sutures are used to close the conjunctiva that are used in the muscle will account for some variation as compared to the technique where the conjunctiva is closed by a separate suture.

3. Whether or not the fascia is stripped entirely from the muscle is also a factor which was touched upon by Dr. Scobee.

4. In the recession operation many points of variation in technique will alter the results.

   a. Whether or not a clamp is used to place the sutures and how far back in the tendon the sutures are placed, or whether or not the fascia is included or is stripped back from the tendon or widely severed, as Dr. Scobee has mentioned, will all affect the amount of correction.

Anatomic variations have already been covered by Dr. Scobee in this and other papers.*

You are all very familiar with functional analysis and many points have been mentioned by Dr. Scobee. When convergence excess is present a weakening of the muscles that have to do with convergence, prorated as to the convergence-divergence relationship, will produce the most satisfactory result. Usually, there is a combination of convergence overaction combined with underaction of the divergence function. Then a combined surgical procedure designed to weaken the muscles having to do with convergence and strengthen the muscles having to do with divergence is best. The amount of surgery to be done on one set of muscles will be prorated according to whether the findings are more abnormal on near or on distance fixation. If the findings are more abnormal at near range, the muscles having to do with active convergence (the medial recti) will be adjusted particularly.

Of course, when one runs across anatomic variations one must also take them into consideration in determining what and how much surgery to do.

One could continue for hours on a more or less futile compilation of the difficulties that beset the attending surgeon in cases of strabismus, but I believe more will be accomplished by the summary of some exemplary cases than in any other way.

In cases of convergence excess combined with a secondary divergence in sufficiency, with a moderate amount of latent hyperopia (over 1.500), and 20/30 vision or better with each eye, the following amounts of recession and resection are planned.

---

* Scobee, R. G.: Am. J. Ophth., 31:781, 1948.

With an esotropia of 35△ for distance and 45△ for near, which is reduced to 25△ for distance and 35△ for near by the use of a nearly full correction of the latent hyperopia present, I have been in the habit of doing first a recession of 4 mm. on one medial rectus and a resection of 5 mm. of the lateral rectus of the same eye.

The technique of the recession was to dissect the conjunctiva and fascia down to the tendon and sever the fascia along the muscle for about 12 mm. and to sever the check ligament as well. One double-armed, 3-0 catgut suture was looped transversely over the central fibers at a point about 2 mm. back from the actual insertion and then the tendon was cut off at the insertion. The needles were then inserted into the outer one third of the sclera at a point 4 mm. back from the insertion.

Strictly speaking this is a recession of only about 3 mm. when the extra amount of tendon in front of the suture is considered and allowance is made for the slight amount of slipping of the suture longitudinally in the fibers of the muscle.

The conjunctiva was then closed with a separate continuous mattress 5-0 catgut suture.

The lateral rectus was likewise cleaned and the check ligament cut. Then a resection forceps was applied to the muscle about 2 mm. back from the insertion. The muscle was then cut off leaving about 0.5 mm. of tendon as a stump. The muscle was then stretched moderately forward and the central needle of a triple-armed suture* was passed from without in through the muscle 5 mm. back from the front of the blade of the resection forceps and then passed forward to the insertion stump.

The end needles of the suture were then passed through the respective margins of the muscle at the same distance back from the blade of the forceps and then passed through the margin of the tendon stump. The suture was then cut at the position of the central needle thus making two sutures. The muscle was then pulled forward and the stump pulled back so there would be no longitudinal slipping of the suture in the muscle. Each suture was then tied, pulling the muscle tightly to the tendon stump. Then the muscle was cut transversely in front of the sutures and the conjunctiva united by a continuous mattress 5-0 catgut suture.

If, in the above case, there had been 45△ of esotropia for distance and 60△ for near, I would have chosen to do a similar recession of 4 mm. and a resection of 7 mm. If more effect is needed an additional recession of 3.5 to 4 mm. on the medial rectus of the other eye would be done.

These figures may serve as a guide, if the above mentioned technique is followed. One could continue this discussion for days but I think that the points that Dr. Scobee has brought out are particularly important. This discussion is specifically prepared from the surgical standpoint since you are all quite familar with the orthoptic points which he has brought out.

131 Fulton Avenue.

THE CLINICAL ASPECTS OF SYMPATHETIC OPHTHALMIA*

HAROLD H. JOY, M.D.

Syracuse, New York

There is evidence that sympathetic ophthalmia was recognized nearly 1,000 years ago, but its first accurate description was given by McKenzie in 1840. Although a vast amount of clinical and experimental investigation has been carried on during the past century, its pathogenesis is still unsolved. Consequently, there is no method of determining individual susceptibility or of ascertaining the imminence of its onset, and there is no specific therapy for its prevention or cure. Attempts to produce the disease experimentally and to find an offending organism have been unsuccessful. The two most generally accepted pathogenic theories are that it is produced by an exogenous infection or that it is the result of an allergic reaction to uveal pigment, or that both processes are involved.

INCIDENCE

Its occurrence is relatively infrequent with an estimated general incidence of about 0.15 percent of all eye diseases and an incidence of 1 to 2 percent of all perforating injuries. It may occur at any age and, although it is most frequent in children, their particular susceptibility has not been proved.[1] Males are much more frequently affected than are females, probably due to their greater exposure to injury.

It has been suggested that certain individuals have an acquired or hereditary sensitivity, and that others, such as Negroes who are rarely affected, have an immunity. Several authors have commented on the rarity of sympathetic ophthalmia in arid climates and have noted the greater likelihood of its occurrence during the wet and cold seasons. For some reason, during times of war, the incidence is lower in the armed

forces than in the civilian population. This has been ascribed to the prompt and proper care of eye injuries of the military personnel, to their better physical condition, and to the possible prophylactic value of the various sera which all receive. It has been stated on numerous occasions that the incidence of the disease has decreased in recent years. However, a review of the literature of the older writers, in which all manner of varieties of ocular inflammation have been diagnosed as sympathetic ophthalmia, indicates that the decrease is more apparent than real.

PREDISPOSING CAUSE

The predisposing cause is almost always a perforating wound involving the ciliary body or the root of the iris, particularly if there is incarceration of uveal tissue or lens material. In such cases the wound does not heal promptly, and the danger of late infection is added to that of immediate contamination and uveal constriction. On the other hand, perforating wounds of the cornea, with a nonprotruding iris prolapse anterior to the limbus, and clean, promptly healing wounds of the sclera behind it, are relatively safe. As a rule, large limbal wounds offer more danger than small ones, since they remain open longer and the uveal prolapse is apt to be more extensive. Strangely enough, sympathetic ophthalmia rarely follows the spontaneous rupture of corneal ulcers. In these cases, the inflammatory reaction produces a fibrinous exudate which soon seals off the exposed area.

The disease seldom occurs unless there is a frank opening in the globe. However, it may follow nonperforating trauma or, more rarely, a disintegrating melanoma of the uvea. In either case there is almost always a subconjunctival scleral rupture, and it is possible that the offending agent enters the

eye through minute abrasions of the conjunctiva, or that it penetrates the uninjured conjunctiva.

The presence of pyogenic bacteria in the globe lessens the hazard of sympathetic involvement by tending to destroy the uveal tissue and whatever is the causative agent. However, it does not provide insurance against its occurrence for some uveal tissue may be retained and, as the globe becomes phthisical, it may become a potentially exciting eye.

About 85 percent of cases result from perforating wounds, and about 65 percent are accidental.[2] The nature of the object causing the injury is relatively unimportant so long as an iridocyclitis is produced. An analysis of 436 proved cases of sympathetic ophthalmia showed that 20.9 percent were attributed to intraocular operations.[3] This relatively high incidence is understandable in view of the fact that most operations involve the iris, and many also involve the lens. Moreover, as the presence of inflammatory or degenerative changes possibly increases the danger, cataract and glaucoma may be of some importance as predisposing causes.

Although it is occasionally impossible to discover an extenuating circumstance to account for postoperative sympathetic inflammation, it is probable that some such cause is frequently present. This was found to be true in 58 percent of 44 confirmed postoperative cases which I studied.[3] In some cases a predisposing pathologic process was found in the exciting eye preoperatively, in others an accident occurred during the operation or shortly afterwards, while in some a second operation was performed. De Grosz[4] has called attention to the fact that repeated operations add to the danger of sympathetic involvement.

Cataract extraction is the most common predisposing cause of postoperative sympathetic ophthalmia. Statistics are not available to show how much of this is due to the frequency of cataract operations, and how much is due to any particular danger of the condition. Extracapsular extraction offers more danger than if the lens is removed in its capsule, because of the greater likelihood of delayed wound healing as a consequence of incarceration of uveal tissue or lens material.

Another important predisposing factor is the development of phaco-anaphylaxis caused by retained lens cortex in the anterior chamber. This is probably the most frequent cause of sympathetic ophthalmia after discission of congenital cataracts.

Although the intracapsular method of extraction obviates the danger caused by lens material, the necessarily large incision favors the occurrence of iris prolapse which, after all, is the most important element in producing sympathetic disease.

Glaucoma operations would seem to offer a favorable field for the development of sympathetic inflammation. For most of the operations which have been devised to relieve intraocular pressure permanently expose the uvea to infection, while the inclusion operations offer the added hazard of iris incarceration.

It has been frequently stated that sympathetic disease does not often follow iridectomy, for generally the operative trauma to the ocular tissues is not marked, iris prolapse is infrequent, and a keratome incision heals promptly and securely. However, three cases followed iridectomy in my series.[5]

Although the deliberate incarceration of the iris seems contrary to good surgical procedure, iris-inclusion operations have become increasingly popular in recent years because of their efficacy in reducing intraocular pressure. Surprisingly enough, it does not appear to be a frequent cause of sympathetic ophthalmia. However, some ophthalmologists have abandoned its use because of this danger. Its substitution by trephination lessens somewhat, but does not eliminate, the hazard; and it offers the added possibility of late pyogenic infection and subsequent loss of the globe.

So long as a glaucomatous eye remains

hard after operation, the chance of sympathetic involvement is remote. However, the very low postoperative tension that sometimes follows may not always be due to filtration, but may be the result of postoperative iridocyclitis. Such a globe is approaching atrophy and may be the precursor of sympathetic inflammation.

Cyclodiathermy and operations for retinal detachment do not favor the development of sympathetic ophthalmia, for the uvea does not prolapse. The reaction causes the openings to close almost immediately and the tissues tend to shrink away from the wound because of their elasticity.

INCUBATION PERIOD

One of the most confusing aspects of this disease is the extreme variability in the interval between injury and the onset of inflammation in the fellow eye. Apparent authentic cases are on record in which this interval ranges from a few days to as long as 49 years. However, in the vast majority of cases, the incubation period extends from 1 to 3 months, with the greatest incidence occurring during the second month. There is usually little to fear after three months have passed, and practically no danger after one year. The diagnosis should be scrutinized closely if the fellow eye becomes affected in less than 14 days after injury or if the interval is greater than one year. Close study of many cases with an apparent extremely long incubation period will show some extenuating circumstances, such as a more recent second injury or operation.

CLINICAL PICTURE IN INJURED EYE

Although there is no characteristic clinical picture in the injured eye to give warning of the onset of sympathetic inflammation, there is usually more or less evidence of the likelihood of impending danger. Eyes which should be viewed with most suspicion are those which, after a penetrating wound involving the ciliary body or the root of the iris, are followed by a prolonged low-grade uveitis which is resistant to treatment and is subject to occasional exacerbations with a tendency to recurring ciliary pain and to phthisis. The danger is in close proportion to the incidence of prolonged inflammation.

On the other hand, the injured eye may give little or no indication that sympathetic ophthalmia is threatening, for the type and degree of inflammation which may be present is almost limitless. It may exhibit the clinical signs of a severe acute traumatic uveitis, or those of a mild inflammatory process that is apparently subsiding without complication. Although the inflammatory signs may be slight, careful examination will show evidence of congestion, for it is always present when sympathetc uveitis appears.

Once sympathetic ophthalmia has started, the congestion in the exciting eye increases and, according to Irvine,[6] runs a parallel course, with exacerbations and remissions occurring coincidentally in the two eyes.

CLINICAL PICTURE IN SYMPATHIZING EYE

Sympathetic ophthalmia may originate posteriorly in the choroid, but it almost always appears first as a mild iritis which gradually develops into a prolonged plastic uveitis, characterized by massive cellular reaction, and subject to exacerbations and recurrences. The iris soon becomes thickened and rigid and more and more resists dilatation. In spite of comparatively mild inflammatory symptoms, exudation is marked, and there is early and persistent development of posterior synechias, and gradual secondary involvement of all the ocular tissues.

With the exception of defective vision the subjective symptoms are notable for their mildness. Ciliary tenderness may be present throughout the course, and pain may occur as the result of an accompanying scleritis or of secondary glaucoma.

The onset is insidious without premonitory signs. Dimness of sight is almost always the first symptom and is usually due to a mild serous cyclitis. Examination at this time reveals bedewing of the corneal en-

dothelium, a few posterior corneal precipitates, and slight clouding of the aqueous. According to Irvine,[6] the corneal precipitates appear in this eye before or simultaneously with their occurrence in the exciting eye. Within a day or two, ciliary congestion can be observed, the iris shows slight furring, a few fine posterior synechias can usually be seen, and the disc is frequently blurred. At the outset, the vitreous is usually clear, but small opacities soon appear and rapidly increase in number, causing a generalized cloudiness and, later, disintegration.

Meanwhile, the inflammation in the anterior segment has continued to progress. The corneal precipitates increase in number, the aqueous becomes more turbid, and the posterior synechias further develop, tending to produce seclusion or occlusion of the pupil. Even if there is partial mydriasis, peripheral adhesions may form, binding the entire posterior surface of the iris to the lens, which shows early capsule clouding and frequently later cataract formation. At this stage the iris has a muddy, velvety appearance and the stroma loses its fine details. Woods[1] describes a characteristic change which usually appears not earlier than the second month in which the iris and lens capsule become almost confluent, with vessels from the iris invading the pupillary membrane.

The media usually become so cloudy after a few weeks as to obscure fundus details. But in arrested cases, small yellowish lesions of chorioretinitis are sometimes seen scattered about the periphery. The intraocular pressure is often reduced and the globe may become very soft but usually some degree of glaucoma occurs as the result of the posterior synechias or of the increased protein content of the intraocular fluids. If this is not relieved, vision is destroyed and phthisis bulbi follows.

Fortunately, early and well-directed treatment usually checks the progress of the inflammation before vision is destroyed. And occasionally there are mild cases which seem to recover regardless of treatment. However, the course is usually long drawn out, characterized by exacerbations and relapses, and lasting 9 or 10 months in the well-treated and favorable cases, and sometimes extending for years in those which progress to blindness.

DIAGNOSIS

The clinical diagnosis cannot be made with absolute certainty since the picture in the exciting eye is not characteristic and may be masked by the results of trauma and infection; and symptoms identical with those found in the sympathizing eye can be due to other causes. The various serologic diagnostic aids, which have been advocated from time to time, have not proved constant; hence, the presumptive diagnosis must be made by ophthalmic signs alone.

The diagnosis will be more likely the more closely the case fulfills the following conditions: (1) The presence of uveal inflammation in the injured eye caused by exogenous infection, particularly if there is inclusion of uveal tissue or lens matter in the wound. (2) A reasonable interval (usually 2 to 3 months) between injury and the onset of inflammation in the fellow eye. (3) The presence in the fellow eye of the rather characteristic plastic uveitis with early development of keratic precipitates. (4) Proof that this inflammation is not due to some other cause such as focal infection, syphilis, sarcoid, or tuberculosis. While a presumptive diagnosis may thus be made, the only means of making a positive diagnosis is by histologic examination of uveal tissue.

PROPHYLAXIS

Sympathetic ophthalmia is much easier prevented than cured. The salient prophylactic measures comprise prompt and proper treatment of accidental perforating wounds, correct procedures in intraocular surgery, and particularly if the progress is not satisfactory, careful and repeated slitlamp studies of both eyes until all danger has passed.

Above all, it is of paramount importance to remove the injured eye promptly if indicated.

Evisceration is not an effective prophylactic measure, probably because of the occasional retention of uveal tissue. Owing to the possiblity of extraocular extension of the process, the enucleation should be done freely, including removal of the muscular insertions and as much of the optic nerve as possible. On the assumption that potentially active material may still be left behind, Samuels[7] has suggested postoperative radiation of the socket.

Although no definite criteria for prophylactic enucleation can be laid down, there are certain rules which, if followed, will lessen the danger of sympathetic ophthalmia. Hopelessly injured eyes and those with vision destroyed by suppuration should be promptly removed. It is also usually advisable to remove blind eyes resulting from old injuries, and even those with light perception but with faulty projection, for they are potentially dangerous. This is particularly true if they are subject to recurrent ciliary congestion and lowered intraocular pressure.

As a rule, prophylactic enucleation is contraindicated if there remains any degree of vision. However, if vision is reduced to light perception in the injured eye and is good in its fellow, enucleation may be indicated in the following conditions: (1) In patients who cannot be controlled. (2) If there is marked ciliary tenderness and low intraocular pressure persisting for as long as three weeks after injury. (3) In extensive wounds involving the ciliary body accompanied by uveal and vitreous prolapse, if not seen within 24 hours after the injury, and in which there is little hope of useful vision.

Sympathetic ophthalmia can always be prevented if the injured eye is removed before the appearance in it of the specific pathologic changes, and it can usually be prevented if removed before such changes occur in the fellow eye. Hence, the shorter the interval between injury and enucleation the greater the prophylactic value. Removal of the exciting eye within two weeks after injury almost always prevents sympathetic involvment, but further delay lessens or nullifies the favorable effect.

If sympathetic inflammation does not follow within two weeks after enucleation of the exciting eye, the chance of it occurring is slight, and it almost never occurs after one month. However, because of the fact that it may appear after a longer interval, it is advisable to make repeated slitlamp studies of the fellow eye for a considerable period after removal of a suspected eye.

If the onset of sympathetic ophthalmia is feared, the pupil of the uninjured eye should be fully dilated in anticipation of inflammation, systemic treatment started, and daily examinations made with the slitlamp.

TREATMENT

To be at all effective, treatment must be started early, and it must be thorough. It is quite generally agreed that enucleation of the exciting eye has little or no favorable effect after sympathetic uveitis is once established. However, cases are occasionally reported which tend to refute this opinion. So, until it has been definitely proved ineffectual, a blind exciting eye or one with grossly faulty projection should be promptly removed, at least in early cases. On the other hand, if it offers any hope whatever of retaining or regaining any degree of vision, it must not be sacrificed, for in the end it may be the better eye.

Practically all that can be done in treating the sympathizing eye is to attempt the establishment of maximum mydriasis. This is usually most difficult, due to extensive posterior adhesions, and to a lesser extent the rigidity of the iris. The development of secondary glaucoma, while potentially very serious, need not necessarily cause undue alarm since, as a rule, the sympathizing eye withstands increased intraocular pressure

fairly well. In many mild cases, particularly if due to increased protein content of the intraocular fluids, the period of hypertension is brief and subsides during the continued use of mydriatics. In others, repeated corneal paracenteses may tide over the acute phase. Any surgical measure involving the uvea should be postponed if possible, for it is notoriously sensitive to operative interference.

No form of systemic treatment has proved entirely adequate. The use of massive doses of salicylates and nonspecific foreign-protein therapy, particularly in the form of diphtheria antitoxin, appear to be the most effective, especially if supplemented by desensitization through uveal pigment. The intravenous injection of arsenicals, tuberculin therapy, and autoserum therapy have many advocates, but have proved of doubtful value. The sulfonamides and penicillin have, on the whole, been most disappointing; and it is yet too early to assess the value of streptomycin.

Because of the devastating nature of the disease, its uncertain etiology, and the lack of a truly adequate form of treatment, there is a tendency to use too many therapeutic agents and to use them excessively. This not only results in confusion of values but may lower resistance to the specific infection. "Shot-gun" treatment must therefore be avoided.

Since the course of the disease is long drawn out and debilitating, the bodily resistance should be aided in every possible way. A complete physical and serologic examination is mandatory, and proper attention must be given to any abnormalties, with particular attention to foci of infection. Bed rest is essential during the inflammatory episodes, and hospitalization is necessary until well after complete subsidence of inflammation in favorable cases, and only when all hope is abandoned in those with an unfavorable outcome. After hospital discharge, repeated follow-up examinations with the slitlamp are most important, for

recurrences and exacerbations are characteristic of the disease.

Even in successfully treated cases the battle with sympathetic ophthalmia is not always won with the subsidence of inflammation, for cataract and glaucoma are frequent complications or sequelae. No conditions tax the judgment and skill of the ophthalmic surgeon more, for while the exciting eye tolerates operations well, the sympathizing eye is extremely sensitive even after a long period of quiescence. This sensitivity may often be reduced by uveal-pigment therapy or by injection of diphtheria antitoxin before the operation. If surgical intervention is necessary, it should be done with a minimum of trauma, particularly to the uvea. Except in a grave emergency, it is advisable to delay the operation for at least one year after all signs of inflammation have disappeared.

PROGNOSIS

The prognosis of sympathetic ophthalmia is always uncertain, chiefly because of variation in degree of severity, the reasons for which are unknown. Many authors have maintained that generally the course is unusually severe and the outcome less favorable in children and after cataract extraction. However, there are too many variable factors present to ascribe importance to any particular type of case. The prognosis is viewed today with much more optimism than in former years, principally because of the earlier recognition of the disease and to a better understanding of the importance of starting treatment promptly. Indeed, the most important prognostic factor over which we have control is the early institution of prompt and proper therapy.

The statistics of various authors indicate that a favorable prognosis may be expected in two thirds of the cases in which therapy is prompt and adequate. The results of my studies would seem to bear this out, for useful vision resulted in 73 percent of the patients for whom treatment was started within two weeks of the onset, compared

with 37.5 percent in those for whom it was delayed for one month or more.[2] Unfortunately, a great many patients are not seen until the disease is well advanced, and the outcome in these cases is likely to be unfavorable in spite of all treatment. Considering all cases, vision of 20/200 or better may be expected in a little over one half.

ARIBOFLAVINOSIS

WITH A CASE REPORT ON PARENCHYMATOUS KERATITIS FOLLOWING RIBOFLAVIN DEFICIENCY

B. K. DAS GUPTA,* M.B.

Calcutta, India

It is barely eight years now that riboflavin has attracted the attention of the ophthalmologists of the world. Since the publication of the paper by Sydenstricker, Sebrell, Cleckley, and Kruse[1] in which they described the ocular signs of ariboflavinosis in man, several workers in different parts of the world attributed different types of lesions of the eye either to riboflavin deficiency or to vitamin-B–complex deficiency. Up until now, no clear-cut picture of ocular manifestations due to riboflavin deficiency has been made out and it is clear that, as the years go by, with the advancement of knowledge, reports of various types of ocular manifestations, which will be attributed to riboflavin deficiency, will pour in.

The components of the vitamin-B–complex group probably act as synergists. In the series of cases described by Sydenstricker, nicotinic acid, thiamin chloride, ascorbic acid, and cod-liver oil were added to the diet in order to make the deficiency of riboflavin a dominating one. Ocular signs may be noticeable before the disorders make their appearance.

Subjective symptoms, such as photophobia and dimness of vision, seem to appear first and on examination circumcorneal injection is seen. The description given by Sydenstricker and others is: "The earliest change that can be recognized with the slitlamp is marked proliferation and engorgement of the limbic plexus with the production of great numbers of very narrow capillary loops which outline the extreme margins of the scleral digitations and obliterate the narrow avascular zone between the plexus and the sclerocorneal junction. . . . Such capillaries lie just beneath the epithelium and soon anastomose to form a tier of loops from which more single capillaries arise, extending centripetally."

Bessey and Wolbach[2] showed that ocular signs of ariboflavinosis could be produced experimentally in rats, and pointed out that the earliest detectable sign is corneal vascularization. Some observers include congestion or engorgement of the normal loops in this category, and Gregory[3] pointed out, in 1943, that there was no discrimination in the literature between a full limbic plexus and an actual invasion of the cornea by new vessels.

Mann[4] says that it would be unwise to include the full limbus among signs of riboflavin deficiency, the earliest certain signs of which would seem to be a budding out

* Professor of Ophthalmology, Medical College, Calcutta.

of new capillaries from the limbal loops at their apices, with extension on to the true cornea.

McCreary, Nicholls, and Tisdall[5] photographed the sclerocorneal junction with the ophthalmic camera and found that the results obtained were not significantly different from slitlamp examination of the corneoscleral junction. Out of 41 individuals studied, who had been provided with a ration containing 2.9 mg. of riboflavin per day for a period of one year, 50 percent were given a supplement of 3.3 mg. of riboflavin three times a day for two months. They did not find any consistent change in corneal vascularization in either the treated subjects or the controls.

Day, Langston, and O'Brien[6] reported on the clinical manifestations in experimental animals on diets deficient in riboflavin. These mainly consisted of alopecia around the eyelids and excessive lacrimation. Pappenheimer reported on the histologic examination of the cornea of one of these rats and found "a very slight keratitis and some newly formed blood channels."

Day, Langston, and O'Brien reported, in 1931, on ocular changes in 37 rats fed on a diet deficient in riboflavin. They found anterior interstitial keratitis in 100 percent and cataract in 94 percent. Microscopic examination revealed an inflammatory process in the anterior stroma. The epithelium was normal but there were subepithelial small lymphocytic and leukocytic infiltrations accompanied by new blood-vessel formation.

In 1935, Bourne and Pyke,[7] in similar experiments, were able to produce cataract in only 31 percent of the animals after a period of 79 days on the diet, and they stated that the most consistent ocular sign was "superficial keratitis," which occurred in 92 to 100 percent of the rats within 70 days.

Das Gupta,[8] in 1943, described a case of parenchymatous keratitis following riboflavin deficiency. In his case the endothelium of the cornea and deeper parts of the substantia propria of the cornea were affected, but there was no new vessel formation at the sclerocorneal junction which invaded the cornea. The patient was given 4 mg. of riboflavin daily and the whole cornea cleared up in 29 days.

Cosgrave and Day,[9] in 1942, reported on 28 patients with corneal diseases treated with riboflavin. The results varied considerably. Cases of interstitial keratitis associated with hereditary syphilis responded much more rapidly when riboflavin was administered along with antisyphilitic treatment than when the antisyphilitic treatment alone was given.

Sebrell and Butler[10] described in detail the general signs of ariboflavinosis in man. The lips may become abnormally red and cracks may appear at the angles of the mouth. There is seborrhea and follicular keratosis of the forehead, malar and chin eminences. The tongue shows signs of glossitis and there may be fissuring of the tongue.

Johnson and Eckhardt,[11] in 1940, reported that rosacea keratitis improved with riboflavin therapy; whereas, recently Fish[12] has contradicted the statement. Karunakaran and Nair[13] described a condition of the skin of the scrotum, in which it becomes dry and scaly and causes considerable itching in cases of riboflavin deficiency along with the eye and mouth lesions (oro-oculo-genital syndrome).

CHEMISTRY AND PHYSIOLOGY OF RIBOFLAVIN

Riboflavin has long been known to be combined with phosphoric acid and a protein to form Warburg's yellow enzyme (Johnson).

B. Warburg's yellow enzyme

Sydenstricker, Kelly, and Weaver[14] maintain that riboflavin, nicotinic acid, and thiamin are the reactive components of several co-enzymes necessary for the fractional dehydrogenating process, which results in the utilization of energy from carbohydrate. Riboflavin is also necessary for intracellular respiratory processes and, like other vitamins, is supposed to be present in every living cell.

It is believed that, if hemin substances are not present in a tissue (for example, avascular cornea), the oxidation within the cell is accomplished by Warburg's yellow enzyme. A deficiency of riboflavin seriously impairs the intracellular oxidative process. Proliferation of capillaries from the limbic plexus seems to be an attempt to combat localized anoxemia by bringing hemin substances into close proximity with the tissues. When riboflavin is administered in sufficient amounts, regression of the proliferated capillaries occurs.

OCCURRENCE OF RIBOFLAVIN IN THE BODY

Riboflavin occurs largely in a free state in secretions such as milk and urine. In tissues it occurs in a combined state with adenylic acid, a phosphate group and a specific protein, most of which do not fluoresce. Prolonged dialysis may release riboflavin from tissues but this is probably due to breakdown of flavoproteins. Estimation of riboflavin depends either on its property of fluorescence, a method described by Najjar,[15] or on the microbiologic method, as worked out by Snell and Strong,[16] that depends on the growth rate of certain bacteria, which varies with the concentration of riboflavin in the medium. The Snell and Strong method of estimation is the one of choice, at the moment, for it enables an accurate estimation of very small amounts of riboflavin. It has been estimated that an adult man requires about 3 to 5 mg. of riboflavin per day.

CASE REPORT

History. P. C. B., a Hindu businessman, a native of Howrah, was seen on October 30, 1947. He gave the history of a slight redness in the right eye followed by gradual loss of vision during the last five months. He was seen by several eye specialists of Calcutta, who gave him atropine drops for his right eye along with milk injections. Wassermann and Kahn tests were negative but still he was given a course of arsenic and bismuth, and to no effect. His vision was very much reduced and he said that his eye was getting worse day by day.

On examination, the right eye showed slight circumcorneal injection. There was slight watering from the affected eye. The photophobia was of moderate degree and there was slight ptosis.

Except for a small rim at the periphery on the temporal side, the cornea was grayish white. There was no encroachment of the limbic plexus on to the cornea. The opacity was almost homogeneous. No keratic precipitates were seen. Vision was 1/60 in the right eye. In the left eye, vision was 6/6 and the fundus was healthy.

On slitlamp examination, it was found that all of the cornea except the epithelium was densely infiltrated. No blood vessel was seen. There were no keratic precipitates. The endothelium was very ragged in outline. Infiltration was much more dense in the posterior part of the stroma than in the anterior part.

General examination. The patient was rather thin but looked quite healthy otherwise. He lived on an average Bengali diet
FIRST STAGE   SECOND STAGE
THIRD STAGE   FOURTH STAGE
Fig. 1 (Das Gupta). Drawings showing the appearance of the eye at various stages during riboflavin treatment. (1st stage) Before treatment was started. (2nd stage) 12 days later after 120 mg. of riboflavin had been administered. (3rd stage) 30 days after treatment was started and after the administration of 300 mg. of riboflavin. (4th stage) After the administration of 520 mg. of riboflavin—at the end of 52 days of treatment. (5th stage) 65 days after treatment was started. 650 mg. of riboflavin had been administered.

FIFTH STAGE

consisting mainly of rice, dal, fish, and vegetables. There were no other signs of ariboflavinosis—no angular stomatitis, glossitis, fissuring of tongue, or scurfiness of the skin of the scrotum.

Treatment. Locally, atropine ointment (1 percent) was applied once every day. He was advised to put on dark goggles. One ampule of Beflavin (Roche) containing 10 mg. of riboflavin was injected intramuscularly every day.

After about 12 injections (120 mg. of riboflavin), the patient showed signs of improvement. The photophobia and epiphora were much less and the corneal haziness looked less dense. Beflavin was continued and, after about 25 injections (250 mg. of riboflavin), the opacity started to clear from the periphery. The patient was given 78 injections (780 mg. of riboflavin) before the whole cornea cleared up. The central part of the cornea was last to clear.

Before the cornea had cleared up completely, the central opacity became fragmented. If anyone had seen the case at this stage, he would have mistaken it to be an old case of superficial punctate keratitis. I personally gave the injections and watched the progress of the case from day to day.

The patient now has a normal cornea, possibly a bit thinned, and his vision is about 6/9.

SUMMARY

1. General ariboflavinosis is reviewed
Before Treatment   After Treatment

Fig. 2 (Das Gupta). Slitlamp appearance of the eye before and after treatment.

with special reference to ocular manifestations.

2. A case of parenchymatous keratitis, which improved markedly with riboflavin given parenterally as the only therapy, is described.

3. Notable features of the case are that there was no abnormal growth of blood vessels from the limbic plexus on to the cornea and that all the layers of the cornea except the epithelium were involved.

FURTHER STUDIES IN AMBLYOPIA

J. B. FELDMAN, M.D.
Philadelphia, Pennsylvania

In a previous paper,[1] I suggested a new device for an easier, as well as more rapid, treatment of amblyopia. Since that time, more experience has been gained both in the use of the instrument and in the phenomena of amblyopia.

Ordinarily the great majority of cases with refractive errors but with normal fundi are corrected by glasses. By comparison the amblyopic cases are few, and these patients are instructed to use either a patch or a mydriatic to the good eye depending on the extent of the refractive error. Unfortunately these instructions are not always rigorously adhered to, and the treatment is discontinued by the patient until the time for the next refraction. When the patient returns after 1 or 2 years for reëxamination and shows a persistently poor monocular vision, the previous tentative diagnosis of congenital amblyopia naturally appears verified, and little more attention is paid to the amblyopic eye.

Undoubtedly amblyopia is a condition far more prevalent than is ordinarily realized. With the aid of the telescopic amblyoscope, one can easily arrive at a prognosis. This will eliminate undue hardship in that the eye need not be patched continuously, and will relieve the examiner of embarrassment because the treatment was not effective anyway.

Associated with amblyopia there may often be a muscular imbalance, suppression, abnormal correspondence, and some or all of these together, with or without strabismus. As a result of these, or possibly independent of these obstacles, there may be a psychologic background, the correction of which may materially affect the improvement or cure in a number of cases.

TREATMENT

Briefly the initial examination consists in taking the vision on four or more different Snellen charts, including the vision through the telescopic amblyoscope. If the latter instrument shows normal vision for the amblyopic eye,* treatment is suggested. An orthoptic examination should be made in order to recognize all the obstacles present. An attempt is then made to correct these obstacles at the same time. The visual acuity is corrected to the best vision obtainable.

Lessons on the telescope are given once a week, with daily lessons for work at home. Twelve lessons are given followed by a month's rest period to assure the permanency of the visual improvement. The patch and some exercises may be used during this rest period. If, on return, the case is not entirely improved, but an examination by the telescopic amblyoscope shows a possibility of further improvement, another course of treatment is suggested. Ordinarily two courses of these treatments have proved beneficial; rarely, are more advisable.

The recession of a line on the Snellen chart on return after the rest period is no bar to further treatment provided the reading on the telescopic amblyoscope approaches normal vision.

It should be remembered that just the attainment of normal vision in an amblyopic eye is not sufficient. The permanency of good visual acuity is assured only when good duction is firmly established, and thus fusion with amplitude is gained. For this reason, associated orthoptic training is necessary.

OBSERVATIONS
AMBLYOPIA ASSOCIATED WITH SUPPRESSION

Ocular, like auditory suppression is a condition often found in normal individuals.

It was interesting to observe what part, if any, suppression played in the presence of

---

* The instrument is more valuable for prognosis in children than in adults.

amblyopia or in delaying cure when treatment was instituted.

Suppression is not an ever-existing obstacle in severe amblyopia, even though one might expect this to be so.

One of my cases will, I believe, illustrate this fact. H. N., aged eight years, with a visual acuity of: O.D., 20/30; O.S., 20/200, took three series of treatments (over a year's treatment including rest periods). Her final vision was: O.D., 20/20; O.S., 20/30. Never during any lesson did she show the slightest evidence of suppression.

On the other hand suppression may be persistent, and yet the patient with amblyopia may have the vision improved in spite of this obstacle. An outstanding case was B. B., aged 32 years. Vision was: O.D., 20/50; O.S., 20/20. She obtained normal vision in five lessons, although she had strong suppression. She could not be persuaded to return for treatment of suppression, a condition of which she was not actually aware.

There were 42 cases of amblyopia, each of which had suppression only. Their ages ranged from 4 to 60 years. Sixteen, or 39 percent, obtained normal vision. In some of these cases, the suppression cleared. Among these, 39 percent of the cases, the suppression varied from mild to alternating to absolute. A number of cases took 2 courses of 12 treatments each with an interval between treatments of one month.

Of the 61 percent of uncured cases, 9 patients had absolute suppression, and the balance varied, like the visually corrected amblyopics, between mild and alternating.

VERTICAL IMBALANCE ASSOCIATED WITH AMBLYOPIA

Any form of muscle imbalance may be asymptomatic, and an individual may also have normal visual acuity of both eyes in spite of either vertical or horizontal muscle imbalance.

Of the various types of muscle imbalance, possibly the only one likely to retard improvement in amblyopia would be the vertical imbalance. White and Brown[2] have called attention to the fact that disregard of the study of the vertical imbalance in a case of squint may result in an unsuccessful operation. Refractionists have seen a number of alternating squints with normal vision in spite of the deviation present.

During the time that the cases of amblyopia were studied, it was interesting to observe that actual improvement in vision came to those patients who, during their treatment, acquired good duction.

The following is corroborative evidence, I believe, that hyperphoria plays a small role, if any, in either the causation of, or as a deterrent factor in the cure of amblyopia.

Hyperphoria can be observed in several types of patients: (1) Those with normal visual acuity and who are asymptomatic; (2) those who attain normal vision and yet have symptoms of muscular asthenopia, such as pain in the eye, dizziness, nausea, and so forth; (3) cases of hyperphoria in squint with normal vision; (4) cases of hyperphoria in squint associated with poor vision.

1. *Hyperphoria* can be present in normal visual acuity as illustrated in this one case. A patient, T. R. S., aged eight years, with a vision of 20/20 of both eyes, came to be refracted. She was examined on three different occasions. There was present during her examination a hyperphoria of between 3 to 9 prism diopters, with alternating suppression. Her vision was normal and, therefore, she did not require glasses.

2. *How little hyperphoria* influenced either the causation or retardation of visual correction is demonstrated by the case of M. S., aged 28 years, who suffered a great deal as a result of her vertical imbalance. She had a left hyperphoria of between 5 and 8 prism diopters, and she wore prisms prescribed for her by several ophthalmologists. Her vision was always corrected to normal in spite of her hyperphoria.

3. *In cases of normal visual acuity*, even in hyperphoria with strabismus, the patient

does not suffer from interference with his vision because of a vertical imbalance. T. A., aged eight years, had an alternating squint of 45 prism diopters. During her orthoptic treatment, her hyperphoria varied from 4 to 14 prism diopters. She even had cyclophoria. In spite of all this, her vision was always normal.

While treating the amblyopic patients, five patients were treated for the improvement of their strabismus. They all had normal vision in spite of the fact that their vertical imbalance ranged up to 13 prism diopters.

4. *Hyperphoria in squint associated with poor vision.*

There were nine patients of this type whose ages ranged from 6 to 16 years, and who had vertical imbalances of from 4 to 13 prism diopters. Their squints ranged to 70 prism diopters. Their vision improved in spite of the hyperphoria present.

In a few other cases which might have been included in this group but were not, there was abnormal correspondence. In these cases, to be reviewed later, the vision did not improve, more likely on account of the abnormal correspondence than the hyperphoria.

STRABISMUS ASSOCIATED WITH AMBLYOPIA

When strabismus is associated with amblyopia there are usually also present other obstacles such as muscle imbalance, suppression, and so forth. These cases were divided into two groups for evaluation: (1) Those with normal correspondence; (2) Those with abnormal correspondence.

1. *Normal correspondence.* There were 22 cases of squint with normal correspondence. Their ages varied from 4 to 44 years. In some cases the squint was as low as 6 to 8 prism diopters* and in others ranged up to 25 prism diopters. Nine patients obtained full correction in spite of the associated ob-

stacles. Of the remaining 13, 5 patients showed no improvement whatever; a few might have improved, but they stopped treatment for one reason or another. Among the patients who did not improve, was 1 with vision of 20/200, and 3 with visions of 20/70.

In the group of improved cases, 2 patients had 20/100 vision and 3 had 20/70 vision in the amblyopic eye. The remaining few had almost the same visional range distribution as the uncured cases in those cases of squint with abnormal correspondence.

2. *Abnormal correspondence.* In this group the ages ranged from 4 to, in several cases, 46 years. The highest angle of squint was 80 prism diopters, yet several squints were as low as 4 prism diopters. One patient had vision as low as 5/200; another, 20/300; 4 had 20/100 vision; and vision in the other cases was between 20/70 and 20/40 for the amblyopic eye.

There were 35 cases of abnormal correspondence. Nine obtained normal vision. Of the 26 cases who did not get well, 5 had a resulting vision varying from 6/200 to 20/200. It is questionable whether the few patients who did show improvement could ever definitely obtain normal vision and, if they should obtain normal vision, whether the cure would be permanent.

Not any of these patients had normal vision on the telescopic amblyoscope on their first or any other examination, so that little hope was expected for these cases from the very beginning. A number of these cases were given 3 or 4 series of lessons, but with no final cure.

AMBLYOPIA ASSOCIATED WITH DIVERGENT SQUINT

There were 4 cases of divergent squint in the group treated; 2 of these cases, with the angle of squint up to 15 prism diopters, were improved to normal.

In the other 2 cases the results were not so good. The angle of squint was 30 prism diopters for each.

---

* For the purpose of uniformity, all measurements were on the synoptophore and are given in prism diopters.

One of these patients, W. E., aged 6 years, had 20/200 vision in the left eye. He took three series of lessons, but vision never improved beyond 20/70. He had a low grade anisometropia.

The other case, H. S., aged 17 years, had an alternating suppression with a hyperphoria up to 5 prism diopters on occasion. Her original vision in the poor-seeing eye improved from 20/50 to 20/40 + 3. She also took three series of lessons. On several rechecks at bimonthly intervals, her vision showed a tendency to recede.

NYSTAGMUS WITH ITS ASSOCIATED AMBLYOPIA

Nystagmus is included in this group only because of the high refractive error in these patients. One could hardly expect amblyopic treatment to improve the visual acuity in a case of nystagmus; there was, however, one exception. The patient had a lateral nystagmus. He came to see me 2½ years ago at which time vision was: R.E., 20/200; L.E., 20/50. He obtained one series of treatments with vision in both eyes improved to 20/40. He returned in five months for a check-up, and the vision was the same. He was not heard from for two years; he then returned because the teachers complained about the poor work he was doing. His vision was 20/70 for both eyes.

A course of treatments was given with resulting vision of 20/40 for the right eye and 20/30 −4 for the left eye. Unfortunately it is impossible to get a true measure of his fixation. However, he feels better and does better work in school, as observed by the teachers.

In the four other cases, the patients claimed that their vision "cleared" and that they felt more comfortable.

PSYCHOLOGIC EXAMINATION AND TREATMENT

When, in the course of treating cases of amblyopia, it was noted that some cases made little progress because of psychologic diffi-culties, I referred 12 of my patients for psychologic examination and treatment. Four of these cases have shown marked improvement in their amblyopic exercises. These amblyopic cases and others to be added will be reported at a later date.

TAKING OF FIELDS AND VISUAL ACUITIES

A number of fields and visual acuities on at least four different test charts were taken on each patient.

The fields, taken in the main on a tangent screen, varied from large central scotoma, to fleeting suppression scotoma of various dimensions, to various-sized scotomas peripherally in the 10- to 30-degree area. A few cases even had a clear-seeing central field up to as far as 10 to 25 degrees, beyond which they did not see.

When such bizarre fields are found for amblyopia, one questions their validity. It is to be remembered that, in the main, the patients are children who, when examined, are apprehensive, and do not give exact findings.

In reviewing the amblyopic records, it was learned that the visual acuities were taken on the most common Snellen charts: (1) Illiterate (E) charts; (2) letters on white charts; (3) numbers on white charts; (4) white letters on black charts. When taking visual acuities with Snellen charts, there may be a personal element involved. Some patients read letters more easily, others numbers. In a majority of the cases, the visual acuity was somewhat less with the number chart than with the other Snellen charts.

ANISOMETROPIA ASSOCIATED AMBLYOPIA

The frequency with which one sees anisometropia in amblyopia is well known. In my cases, 63 patients had an anisometropia of more than 1 diopter; 25 had an anisometropia up to 1 diopter.

It was interesting to observe, in reviewing several thousand records taken at random from my files, that 68 patients had anisometropia and 20, a milder form; that is, a varia-

tion in refraction of up to 1 full diopter. All these were amblyopic.

In addition to this number, there were 49 patients with anisometropia among 2,000 patients. Not a single one of these 49 patients had amblyopia, showing that anisometropia, unless of high degree, is not the sole cause of amblyopia.

The degree of anisometropia or the vision present were not always indications as to whether the case would not respond to treatment. Some cases with a high visual error improved faster then those with better vision, and the same was true in anisometropia.

SUMMARY

A review of 108 cases of amblyopia is given; 36 (32 percent) were cured.

Directions are given for the use of the telescopic amblyoscope as a prognostic instrument and for the treatment of amblyopia.

Obstacles are diagnosed by orthoptic examination.

To obtain permanency of the improved vision in an amblyopic eye, it is important to obtain, in addition to the improved vision, fusion with amplitude. Vision should be rechecked on a number of occasions for a number of months.

Suppression, muscle imbalance, squints with or without normal correspondence are discussed as to their relative importance in the causation or delay of cure of amblyopia; excepting the cases of congenital amblyopia which are always incurable.

Anisometropia and squint with abnormal correspondence, or amblyopia with a high angle of squint, may be instrumental in either the causation, the prolongation, or failure of cure in amblyopia.

It appears that if the adult past the age of 45 years and the conditions just mentioned are excepted, there is some hope for the amblyopic.

With the telescopic amblyoscope, or some such devise, a prognosis for the case can be given, especially for a child. The telescope has an added advantage—that of being used in treatment.

Poor visual acuity (less than 20/200) is not always an indication of a poor result. A patient with a visual acuity of, for example, 20/40 in some instances has no better assurance of improvement than another patient with vision of 20/70 or 20/100. The same is true of anisometropia. Amblyopia with a very low degree of anisometropia may sometimes take longer to cure than when a slightly higher degree of the same condition is present.

CLINICAL EVALUATION OF D.F.P. IN GLAUCOMA THERAPY*

MORGAN B. RAIFORD, M.D.

Atlanta, Georgia

Since its introduction for the treatment of glaucoma, D.F.P. has proved a most potent anticholinesterase drug and a powerful miotic. Its action is quite prolonged and, according to Scholz and Wallen in their studies in normal human eyes, signs and symptoms of its spasm of accommodation and miotic effects varied from 3 to 7 days following a single instillation.

D.F.P. in the concentration of 0.05, 0.1, and 0.2 percent produces blurring of the vision, headache which may be over the eye, or orbital discomfort. Spasm of accommodation and pericorneal injection are frequently encountered. McDonald stated that the ciliary spasm and occasional rise in tension following its administration apparently is the result of arteriolar dilatation and an action of the drug upon the ciliary body. In the concentrations already mentioned, it produces its greatest number of undesirable symptoms during the first few days of its use. Because of these effects, there has been a tendency to discredit the use of D.F.P. in the clinical care of glaucoma patients. In the toxicologic studies reported, no dangerous side reactions have been noted when the concentrations usually given in glaucoma cases have been administered.

Leopold and Comroe reported two instances in which a rise in intraocular pressure followed instillation of D.F.P. In one of the cases, an iridectomy was required before the tension fell spontaneously.

In the 82 patients with 122 glaucomatous eyes, reported by McDonald, 57.4 percent had a tension of lower than 30 mm. Hg (Schiøtz). In McDonald's series, 0.1-percent D.F.P. was used in daily instillations. He also noted that the correct dosage must be determined for each patient.

The use of D.F.P. (0.05 percent) following intracapsular cataract extraction through a round pupil and in cyclodialysis is recommended by Lebensohn as a miotic of choice at the conclusion of surgery.

PRESENT STUDY

Since D.F.P. has such prolonged action and is a most capable antagonist of cholinesterase, a series of 22 patients with 42 glaucomatous eyes were studied, using varied concentrations of the drug. The period of investigation covered a period of 10 months.[†] The patients, with two exceptions, had had glaucoma for a period of from 10 months to 9 years.

When first used, D.F.P. (in each case 0.05 percent or 0.1 percent in peanut oil) was instilled as one drop at bed time every night. This was continued for 2 to 4 weeks, and the effects as to signs and symptoms were recorded. The D.F.P. was then discontinued for a period of 4 to 6 weeks, during which time miotics previously used were given. Then D.F.P. of lesser concentration was used, 0.01 percent and 0.005 percent in peanut oil), one drop being instilled nightly at bed time. This was continued for the remainder of the 10 months of observation with the exception of two cases.

Of these exceptions, one patient was found to be sensitive to peanut oil (Case 20), and another (Case 17) was probably refractory to the drug and was returned to 5-percent pilocarpine which was instilled 5 times a day in each eye.

SURVEY STATISTICS

In this series of 21 patients with 41 glaucomatous eyes, the age varied from 39 to 84

TABLE 1

TABULATED CLINICAL FINDINGS WITH ADMINISTRATION OF D.F.P. IN THE TREATMENT OF GLAUCOMA

No.	Name	Age	Type and Duration of Glaucoma	Vision	Intraocular Pressure with Previous Miotics (mm. Hg Schiotz) Lowest	Highest	Average	Previous Therapy	Visual Fields	D.F.P. No reaction and H.S. X1 daily. Tension variations less.

years. Chronic simple glaucoma was present in 17 patients or 33 eyes; secondary glaucoma was present in 4 patients or 8 eyes. The secondary glaucoma followed postcataract extractions in 4 eyes, an old keratitis in 2 eyes, and iridocyclitis in 2 eyes. The duration of the glaucoma in this series varied from 10 months to 9 years.

EYE EXAMINATIONS

Visual acuity. This was the best vision obtainable with the patient's correction. All cases were refracted before the survey began and again during the last three months of the study.

Gonioscopic examination. A gonioscopic examination was made of each patient at the beginning of the investigation. When administration of 0.05- and 0.1-percent of D.F.P., was started, gonioscopic examination was again done. No noticeable change was noted in the iris structure under gonioscopic vision after use of D.F.P.

Tension. Intraocular pressure was recorded (Schiøtz) before the D.F.P. was given, and tension curves since the patients were first seen were reviewed. After D.F.P. was begun, both in the first series (0.05 percent and 0.1 percent) and the second series (0.01 percent and 0.005 percent), tension readings were taken every day for 4 days, and signs and symptoms noted; then they were taken each week. The highest, lowest, and average tension readings were recorded for previous, as well as D.F.P., therapy.

Visual fields. Central fields were taken in each case before D.F.P. therapy was begun. The fields were all done under 7 foot-candles in artificial light (light was standardized and checked at monthly intervals with a light meter). Visual fields were done every two months. An evaluation of the field changes was made at the end of the 10-month period of investigation (table 1).

SUMMARY

In a series of 41 glaucomatous eyes followed over a period of 10 months, 33 eyes had chronic simple glaucoma and 8 secondary glaucoma.

In 13 patients (25 eyes) one drop of 0.1-percent D.F.P. was instilled at bed time. With the exception of two eyes (Case 3), the patients noted headache, ocular discomfort, blurring of vision, and extension to the sensation of pain. A concentration of 0.05 percent in 8 eyes (Cases 4, 12, 13, and 15) caused only slightly less reaction of similar nature, with the exception of Case 4 in which only a slight rise in intraocular pressure was evident during the first two days. One case (7) was begun with 0.01-percent D.F.P., and no reactions occurred of any type throughout the period. One patient (20) was sensitive to peanut oil, determined by instilling it in each eye after a 4-week free period of D.F.P. Only one individual (17) proved to be what was considered refractory to D.F.P. and the intraocular pressure went up to 56 mm. Hg at the end of five days. The tension returned promptly to an average of 21 mm. Hg and was maintained well with 5-percent pilocarpine.

After an interval of 4 to 6 weeks in which the patients were returned to pilocarpine or eserine therapy, they were placed upon 0.01-percent D.F.P. in 19 cases or 36 eyes. Two patients (13 and 15) or 4 eyes used 0.005 percent D.F.P. with similar results. In two eyes (Case 8), the optimum concentration of D.F.P. to control the tension properly proved to be 0.02 percent. In 18 eyes, 0.005-percent D.F.P. proved just as effective in maintaining proper tension as the 0.01-percent solution.

The tension curves were better maintained with 0.01- or 0.005-percent D.F.P. in all cases with exception of one eye (Case 8). The entire study showed that fluxations of intraocular pressure were decreased by 28.5 percent and an overall reduction in level in tension of 17.4 percent.

The visual fields were not expected to change too much. One case (19) showed the greatest single increase of the central fields. In Case 8 the presence of Seidel's sign dis-

appeared in both central fields, which is attributed to the more stabilizing effect of D.F.P.

The most frequent comment of the patients was in praise of the ease and need of less frequent instillation when D.F.P. was used. Since D.F.P. was given at bed time, the film created by the peanut oil was less annoying. With the exception of Cases 17 and 20, the patients have been pleased with this miotic and prefer it to previous medicants. They stated that their vision was clearer throughout the day when D.F.P. was used.

CONCLUSIONS

1. The use of D.F.P. in lower concentration (0.01- and 0.005-percent) has proven it a most valuable miotic in the clinical care of *glaucoma patients.*

2. The maintaining of a lower and less fluctuating intraocular-pressure curve has been constantly demonstrated throughout the entire 10-month period of this study.

3. The prolonged effect of the drug lessens the frequency of instillation, and the use of more than one drop daily did not lower the tension curves.

4. No detrimental reactions have been manifested in the concentrations of 0.01- and 0.005-percent D.F.P.

OPHTHALMIC MINIATURE

The subdivision of manual labour manifestly tends to perfect the operations of art; but to limit the sphere of Science by the detachment of its parts, is to destroy the foundation upon which it rests. With respect to that of Medicine, however beneficially we may observe the labours of individuals to be occasionally exerted in the selection of particular branches, as the more exclusive objects of their study and attention, yet this can only occur to those who have first investigated this science as a whole; and we may be assured that others who assume a superior knowledge of any branch of medical practice, on the ground of comparative ignorance of, or indifference to the rest, are but little indebted for whatever reputation they acquire, to the actual benefit they are able to effect.

JOHN VETCH, *A Practical Treatise on the Diseases of the Eye,* 1820.

NOTES, CASES, INSTRUMENTS

THE EFFECT OF DI-ISOPROPYL FLUOROPHOSPHATE (D.F.P.) ON THE PUPIL OF THE DARK-ADAPTED EYE*

Edwin B. Dunphy, M.D.
Boston, Massachusetts

Englehart[1] in 1931, using rabbits and cats, showed that, when the third nerve was stimulated, a substance was liberated in the aqueous, which had the properties of acetylcholine. It was found to be greatly increased when the eye was exposed to bright light, but it was absent in the dark-adapted eye even

Fig. 1 (Dunphy). Normal appearance of the eyes of subject used in the experiment.

after eserine had been instilled to destroy the cholinesterase.

This being the case, one might infer that the anticholinesterase miotics would have little, if any, effect on the pupil of the dark-adapted eye, since no acetylcholine would be formed in the dark to stimulate the sphincter muscle of the iris. However, Englehart also demonstrated the presence of acetylcholine in extracts of the iris or ciliary body not only of eyes that had been exposed to light, but also of those which had been kept in the dark.

It is true, of course, that during sleep the pupils are miotic, but this might be the result of unconsciousness in which the stronger sphincter tonus prevailed over the dilator tonus due to the removal of inhibitory sympathetic stimuli.

It has already been shown[2] that, if a human eye is exposed to D.F.P. vapor and immediately dark-adapted for one hour, the miosis persists in the dark in spite of the fact that no reflex impulses from light stimulation are travelling over the third nerve. This suggests that the acetylcholine formed in the tissue just prior to dark adaptation cannot be eliminated in the absence of cholinesterase.

A search of the available literature failed to show whether or not an anticholinesterase miotic would produce any miosis if instilled into an eye *in the dark* after complete dark adaptation. The following experiment was therefore devised to ascertain the answer to this question.

A young individual with normal pupillary responses (fig. 1) was dark adapted for 30 minutes in front of a high-speed camera already focused to take a flash photograph of the pupils. At the end of this period of dark adaptation, one drop of D.F.P. (0.05-percent solution) was instilled in the left eye. This was accomplished by means of a special eyecup originally devised by Heath,[3] and modified so that the subject could instill the drop in his own eye in complete darkness without fear of injury to the cornea. Dark adaptation then continued for another 30 minutes, the flash photograph being taken at the end of this period (fig. 2). This shows the right pupil widely dilated, but the left pupil miotic.

Fig. 2 (Dunphy). Appearance of eyes after dark adaptation and instillation of D.F.P.

It is obvious from this experiment that D.F.P. will produce miosis when instilled in complete darkness in a dark-adapted eye when no reflex impulses (at least from light stimuli) are traveling along the third nerve. This seems to corroborate the belief generally held among pharmacologists and physiologists that acetylcholine is constantly being formed at all parasympathetic nerve endings as the result of normal muscle tonus.

PROGRESSIVE RETINOPATHY ASSOCIATED WITH MENSTRUATION

GEORGE R. LAUB, M.D.
Columbia, South Carolina

History. E. H., a 13-year-old white girl, was seen for the first time on August 9, 1944, with the complaints of slightly diminished vision. She was brought by her parents in order to have some glasses fitted. The examination at that time showed a visual acuity of 20/20 in the right eye and less than 20/800 in the left eye. The external findings for the right eye were perfectly normal, with normal eyegrounds.

The left eye showed some yellowish pinpoint spots between the disc and the macula. They had a peculiar arrangement in so far as they were all within a triangular field with the base at the disc and the apex of the triangle at the macula. The best description of these spots would be that they looked like beginning miliary tubercles.

No diagnosis could be made at that time. The patient was given some simple eye wash for psychologic reasons and was asked to return in a week.

Second examination. On August 16, 1944, the right eye was unchanged, the vision of the left eye was 20/228, the already described spots in the eye had practically disappeared. Her mother told me that during the last week my patient had had her first menstrual period.

On August 30, 1944, she was reëxamined and the vision of the left eye was 20/80. No spots at all were on the retina. On September 13th, the second menstrual period had not yet started, and vision of the left eye was 20/200, with the spots like they were at the first examination.

At that time, the child was admitted to the Columbia Hospital for thorough examination. The medical findings were all negative. X-ray films of sinuses, skull, and chest were all within the normal limits. Urine, blood count, Wassermann, tuberculin, and undulant-fever agglutination tests were negative. Glucose-tolerance test was normal. B.M.R. was normal.

Course. On November 15, 1944, vision in left eye 20/320, the spots reappeared, and at the upper side of the triangle a slight grayish tissue like a fold could be seen. The right eye, during the entire period of observation up to the present time, had always been normal.

Because of trouble with her menstrual periods, which were very irregular, she received at the advise of her diagnostician (Dr. F. E. Zemp) Antuitrin S and some Theelin injections. Her eye condition kept on changing with each period, worse just before the menstruation, best shortly afterwards.

For many months the parents did not return her, but, in February, 1946, when she returned, an entirely different picture was presented. The left eye showed that "the

disc is somewhat paler than the right and, extending out into the vitreous body from the disc towards the macula at an angle of perhaps 10 degrees with the retina, is a gray-

Fig. 1 (Laub). Eyeground of the left eye. (Published with the kind permission of Dr. B. Anderson, Duke University Hospital.)

ish white sheath. This is not associated with a vessel. It is approximately a fourth of a disc diameter in width and appears almost as a fibrous cylinder with tenestra or dehiscences at irregular intervals in the walls. The tip extends well over the center of the macula and from the tip a few darker strands dip down to the macular area. The retina in the macular area is drawn upward toward this tip almost like a tent.

"As viewed with a giant binocular ophthalmoscope, one gets the impression that this tubular whitish sheath hangs out in a cranelike fashion from the disc and, at its tips, raises the retina in a tentlike fold over the macular area. Beneath this tentlike fold in a roughly oval disc about the diameter of which is a dark-brown or black area that is interpreted as being choroidal or subretinal hemorrhage. Extending from the disc vertically to the 3-o'clock position is a fold of retina which would ordinarily be interpreted as a congenital anomaly (retinal septum)."

This quotation is from a report of Dr.

B. Anderson at Duke University Hospital, who saw her in consultation and took the photograph at that time (February, 1946), which he kindly permitted me to use for publication (fig. 1). The vision of the left eye was 20/200.

A year later, in March, 1947, the findings of the eyegrounds were apparently unchanged, although the vision dropped to 20/400−. In June, 1948, when I saw this girl last, her vision was unchanged (20/400) but practically no central vision was left. The "tent" as described by Dr. B. Anderson, which used to have a veil-like appearance, increased in density and progressed somewhat further encasing practically the entire macula. The upper part of the tent had an especially dense appearance.

Comment. This case is a very unusual one. There is no heredity factor involved. We had the chance to examine the eyes of the parents, as well as other members of the family, none of whom showed any sign of a pathologic condition of the eyes.

The picture of the eyeground as it appears now could easily be mistaken for that of retinitis proliferans. However, having observed the entire development of the disease over a period of more than four years, having seen the changes of the eyeground with each menstrual period, at first only "miliary tubercles" later the development of fibrous tissue, makes the diagnosis completely obscure. A search of the entire literature and personal discussions with some of the leading ophthalmologists did not throw any light on this case.

SUMMARY

The case of a young girl, whose eyesight as well as eyegrounds changed with each menstrual period is reported. She is gradually loosing the sight of one eye. No description of a similar disease could be found in the literature. It is hoped that, if any ophthalmologist can throw light on this case, he will communicate with me.

DIFFERENTIATION OF CONJUNCTIVAL TUMORS

CLINTON WILSON, M.D.
Los Angeles, California

It is sometimes difficult without histologic study to different pinguecula and early pterygium from early malignancy of the conjunctiva. Missed diagnoses are not unknown. Therefore, some practical means of giving at least a hint of possible malignancy should be useful.

One such means is the use of the Hildreth or the Woods lamp. The ultraviolet light emitted by these lamps causes fluorescence of the lipoid-bearing pingueculas and pterygia but not of the lipoid-free but otherwise similar-appearing structures which may be malignant.

Attention is directed to the matter at this time because of: (1) Confirmation of preoperative diagnoses of cancerous or precancerous lesions made on the basis of nonfluorescence, and (2) the need for widespread investigation, histologic and otherwise, in order to evaluate the worth of this simple procedure.

Such a study might disclose that some fluorescent lesions are malignant and that some nonmalignant lesions are nonfluorescent.

It is good clinical practice at this time, in my opinion, to be suspicious of and therefore to excise thoroughly the nonfluorescent conjunctival lesions. The reports of histologic study of such material would be valuable.

A PENLIGHT PROJECTOR FOR THE LANCASTER RED-GREEN MUSCLE TEST*

JOHN M. HILL, M.D., AND
FENN T. RALPH, M.D.
New York

This test, devised by Lancaster[†] for the measurement and interpretation of muscle
Fig. 1 (Hill and Ralph). (A) Assembled penlight. (B) Focusing sleeve. (C) Red and green disks. (D) Penlight barrel. (E) Penlight batteries —size AA Eveready. (F) Reid-streak retinoscope bulb.

deviations, involves the use of two flashlight projectors. However, the fact that the commercial projectors are cumbersome, expensive, and not readily available discourages the use of this test by the ophthalmologist.

In attempting to overcome this difficulty, the following inexpensive penlight projector was devised. A simple two-cell penlight is utilized, with a straight filament bulb[‡] as the source of the illuminated streak. Two condensing or focusing sleeves,[§] one fitted with a small round disk of red plastic, the other with green, slip over the barrels of the penlights and focus the streaks thus produced, at the desired distance of 1 or 2 meters.

In addition to its primary use with the Lancaster red-green test the projector has a secondary function. By removing the red or green plastic disk in the focusing sleeve, the projector, with its illuminated streak, can be used for external eye examination. It may also be used in conjunction with a loupe as a hand slitlamp for examination of the cornea, anterior chamber, and lens.

BIOMICROSCOPIC OBSERVATIONS OF THE CHAMBER ANGLE WITH THE GONIOPRISM

Dr. Harvey E. Thorpe said that the first goniobiomicroscopy was performed by Koeppe in 1920 with the aid of his contact lens, a special mirror, and the slitlamp microscope. The technique was difficult and was usually limited to the examination of the nasal and temporal portions of the anterior-chamber angle. Clinical interest in this region of the eye dates back to Leber's demonstrations, in 1873, that the trabecular portion of the angle was the chief exit channel for the aqueous fluid. Further interest was aroused when Knies, in 1876, having discovered the anterior-chamber angle to be obliterated in glaucoma, postulated the closure of the angle to be due to inflammation. One year later, Weber brought forth the view that edema of the ciliary body and processes was responsible for occlusion of the angle.

Trantas of Athens, in 1900, and Saltzman of Graz, in 1914, were the first to publish chamber-angle studies. In this country Troncoso was first to call attention to the contact-lens method for clinical examination of the angle in 1921. It was really Troncoso's work and his invention of aids to gonioscopy which gave this subject its clinical basis. Castroviejo, Reese, and Bruce were among the early workers in this field. Friedman simplified the method of filling the space beneath the contact lens with fluid. Kronfeld, McLean, Sugar, and others have shown the value of gonioscopy for anterior-chamber surgery.

It was Barkan, however, through his studies of the angle and his new approach to glaucoma surgery, who gave this subject further impetus in the 1930s.

Since then, the advent of the Goldman contact lens and more recently the Allen gonioprism have facilitated the examination of this region with the aid of biomicroscope. Two drops of 0.5-percent pontocaine are instilled in the conjunctival sac. A drop of 1-percent methyl cellulose is placed on the concave surface of the plastic gonioprism and the instrument, with its flat reflecting surface below, is inserted between the lids while the patient is seated at the slitlamp.

The slit illumination is thrown into the prism mirror surface and the microscope is focused in the same area to observe the magnified view of the upper angle. The prism is readily rotated within its plastic speculum carrier to observe the entire circumference of the angular drainage area.

Narrowing of the angle, adhesions between the iris root and peripheral cornea, pigmentation or debris or exudate in the trabecular zone are readily recognized by this means. Small foreign bodies hidden behind the limbus within the angle, small pathologic conditions of the peripheral iris, and trauma can only thus be recognized. Moreover, inflammatory corneal processes and keratic precipitates can thus be seen from the posterior view. If corneal edema presents a problem, a drop of glycerine usually dehydrates the cornea sufficiently to facilitate both angle and fundus studies. One of the benefits resulting from this technique is the ability to study our own handiwork after glaucoma and cataract surgery. We can thus tell why we fail in one cyclodialysis or trephination and succeed in another, and why a cataract extraction with delayed chamber restoration frequently results in subsequent

glaucoma. Gonioscopy has aided in our understanding of the pathologic processes of the visible angle and helps in planning the medical and surgical management of cases in which the chamber angle is concerned.

CIRCULATORY ASPECTS OF THE GLAUCOMA PROBLEM

DR. JOHN N. EVANS delivered the annual Mark J. Schoenberg Memorial Lecture. He discussed certain aspects of ocular circulation. He called attention to the fact that the aqueous and the vitreous might be termed the "fourth circulation." (The "third circulation" was a term created by Harvey Cushing in referring to the cerebrospinal system fluid.) He presented illustrations from original work which lent strength to the idea that the vitreous is probably much more active in a nutritive and dynamic sense than is usually recognized. He suggested that the remains of the vitreous vascular fetal system may act as cleavage planes to help conduct the aqueous element of the vitreous to the posterior drainage system by way of the perivascular spaces.

He pointed out that the choroid in health is much thicker than we are led to believe from the study of histologic preparations. He discussed the possible mechanism of vitreous-chamber fluid pressure associated with the rapid changes in volume of the choroid which take place in nervous shock, and so forth. The mechanism taking part in such changes is related to the action of the so-called capillary sphincter muscles, the structure which he described in a communication about a year ago. He stressed the point that therapeutic and surgical measures should be designed especially for the relief of vitreous pressures in cases of glaucoma. Dr. Evans illustrated his paper with numerous slides from original studies. (The lecture will be published in an early issue of the JOURNAL.)

Bernard Kronenberg,
Recording Secretary.

LOS ANGELES OPHTHALMOLOGICAL SOCIETY

December, 1948

DR. WILLIAM ENDRES, *chairman*

THE TEXTBOOK RETINA AND THE REAL ONE

DR. GORDON L. WALLS of Berkeley (by invitation) presented an illustrated lecture correcting many of the errors and half truths concerning the retina as described in most textbooks.

The retina does not end at the ora serrata, but at the margin of the pupil. In lowly vertebrates the sensory retina degenerates if the opticus is cut, but a new retina regenerates from the ciliary epithelium, which is actually retinal tissue.

The retina is not a mere part of a sensory organ. It is the visual sense organ, and more. All other parts of the globe are as much accessory as are extraglobar orbital structures. The retina is homologous with the whole thickness of the brain wall, and is more a sense organ since it contains its own associational systems mediating facilitative and inhibitional phenomena, and can almost "think."

The retinal layers traditionally taught have no meaning. Functionally, the retina has only four layers: (1) the purely nutritive pigment epithelium; (2) the visual-cell layer; (3) the layer of internuncial neurons; and (4) the ganglion, so thinly distributed that it forms a "layer." At either side of the internuncial layer, funneling and spreading of excitation and inhibition are mediated by the horizontal and amacrine cells and by the diffuse dendrites of large bipolar and ganglion cells.

Rods and cones are neither nerve cells nor neuro-epithelium, but modified ependymal cells which were formerly flagellated, as is shown by their cytogenesis as well as by their situation in the developing optic cup.

The rods are not historically older than the cones, as is generally taught (and as is

assumed in the Ladd-Franklin theory of color vision). But the first cones did not mediate color vision—nor did the first rods contain visual purple, which is by no means a primitive visual photochemical but an ingenious one which conveniently decolorizes in bright light (preventing dazzlement).

Cones have secondarily given rise to rods, and vice versa, through evolutionary transmutations. The two are not immutable structural types. Pure-cone, diurnal animals have had nocturnal descendants with duplex and even pure-rod retinas. Human cones were derived from lemuroid rods and are not homologous with cones outside of the Primates.

Human cones are not conical. Adequate micrologic methods show their outer segments to be cylindrical and as long as those of rods. Moreover, each cone outer segment is ensheathed by (and possibly continuous with) a tubular process from the nearest pigment-epithelium cell. This trophic arrangement, demanded by the elevated metabolism of the cones (as opposed to rods), explains why vision never returns perfectly after a detachment is repaired.

The cones are not most numerous in the extramacular fundus and fewest at the ora; nor are the rods most numerous at the ora. Østerberg found the densest rod population in a zone only 5 to 6 mm. from the fovea. The rods are actually denser here (160,000/sq. mm.) than are the cones in the fovea.

What the textbooks call the "macula" is actually the *area centralis*. The fovea, properly, is the depression in this area. The macula lutea is by definition the region containing a yellow pigment. With a purple filter described by Walter Miles, the macular pigmentation can be seen entoptically. It is found to be actually smaller than the foveal pit, though textbooks describe the fovea as occupying a small portion of the macula. The human area centralis may have a diameter of 10 to 12 degrees, the foveal pit 6 to 7 degrees, the macula lutea 2 to 2.5 degrees; and, the rod-free spot is only 50 minutes of arc in diameter. The cones in this spot are slenderized to promote acuity and elongated to preserve their sensitivity.

The center-to-center separation of adjacent foveal cones is 24 to 28 seconds, which happens to be about the value of the smallest resolution thresholds reported for Landolt-ring targets. But this is mere coincidence. Resolution thresholds may be made as small as desired with parallel-line targets, simply by increasing the thickness of the lines. The resolution target then intergrades with one presenting a bright line on a black field, and for such a line there is no minimal visible width.

Resolution of lines does not require an unstimulated row of cones between stimulated rows, hence is not limited by the diameter of one cone. It is only necessary that the rows of cones be differentially stimulated; so, it is the intensity-discrimination function that sets the limit upon visual acuity: in resolution, one is discriminating intensities within the diffraction retinal image of the target. The conception of the mental image as being made up of dots, each contributed by a cone, is fallacious and outmoded.

The "retinal local signs" so important in space perception are neither retinal nor local, but cortical and directional. The stimulation of a retinal point arouses a cortical point which now has information regarding oculocentric direction but not of distance, hence not of place. Space is more finely graduated than is the visual-cell mosaic (as vernier and motion acuities show), since the multiplication of paths between the cones and the cortex makes a great number of cortical elements correspond to two adjacent cones. Differential illumination of these cones can cause activity to "peak" in any one of many cortical cells, so that the spatial point may be directionalized between the produced axes of adjacent cones. Visual space is thus made subjectively "continuous."

Orwyn H. Ellis,
Recorder.

OPHTHALMOLOGICAL SOCIETY OF MADRID

May 14 and June 18, 1948

HYDATIDIFORM CYST OF ORBIT

DR. MARIN AMAT AND DR. BENZO, in discussing the surgical cure of a hydatidiform cyst of the orbit, referred to the case of a 5-year-old boy who had had intense pain in his left eye for 2½ months and awoke one day to find his lids greatly swollen. During the 2 or 3 days that the lids remained swollen, the pain was gone. The cycle repeated itself every 3 or 4 days.

Examination of the left eye showed a pronounced, irreducible exophthalmos; very marked edema of both lids, especially the upper; slight erythema of the skin of the lid; almost complete limitation of ocular movements; sensation of a fluid wave in the upper inner angle of the orbit; and visual acuity of ¼. The fundus showed a white papilla, with sharply defined borders and normal vessels, that is, a developing, simple (descending) atrophy. Laboratory findings gave a red blood count of 5,040,000; leukocytes, 10,700; eosinophiles, 6; lymphocytes, 50. The Arneth index showed a deviation to the right, the intradermal reaction of Cassoni was positive after 6 hours, and positive after 24 hours.

A Krönlein operation was performed and, at the apex of the orbit, situated between the superior rectus and the inferior rectus, was a cyst, the size and shape of a small date, having a thin covering which broke during the dissection and poured out a colorless transparent liquid. The operation was completed by repositioning the osteo-musculo-cutaneous tissue.

The postoperative course was followed by an intense inflammatory reaction (of an allergic nature) which lasted nearly a month. At the end of this time, a cure was obtained with conservation of vision and a perfect cosmetic result.

Discussion. Dr. Mario Esteban opened the discussion by saying that Dr. Marin Amat had reviewed the symptomatology and differential diagnosis of hydatidiform cysts of the orbit so completely that there was nothing to add. He only pointed out that one must not ascribe an absolute role to the eosinophilia, since it is absent in some cases, and on the other hand may be present in tumors, as in sarcoma. Puncture for diagnostic purposes must not be done without taking precaution against an anaphylactic shock.

As for treatment, surgical extirpation is better than injection of modifying substances. The latter method should be reserved, as in the early days of marsupialization, for those cases where the extirpation is difficult or where, because of the situation and adhesions of the cyst, important organs have to be sacrificed in the operation. However, he recommends to puncture the cyst with a syringe before the operation in order to remove some of the contents, taking care not to spill any of the hydatid liquid on the tissues and, without retracting the needle, inject some formalin into the cavity before detaching the membrane, which ruptures easily. Evacuating the contents of the cyst leaves the membranes flaccid, which facilitates the extirpation, and the injection of formalin is useful for its sterilizing effect.

CYSTICERCUS OF THE VITREOUS

DR. MARIN AMAT AND DR. MARIN ENCISO presented a man, aged 39 years, who had lost the sight of his right eye a year and a half before, after a period of violent pain and acute inflammation, and who for the past several days has noticed complete, momentary lapses of sight in his left eye.

Examination showed in the vitreous of his left eye a cylindrical shaped vesicle fairly large and of a bluish color, with a rounded end at the upper part of the fundus and at the other end a thin and long, necklike structure which ended in a rounded area, like a head. The vesicle displayed lively movements of displacement and contraction, especially of the head and neck of the parasite, which reminded one of the antennas of a snail.

The right eye showed an atrophic iridocyclitis, perhaps also of a parasitic origin. Laboratory tests were negative to the Wassermann, urine, Weinberg, and Cassoni tests. Erythrocytes were 3,650,000; leukocytes, 4,800; eosinophiles, 2; and lymphocytes, 27 percent. The patient was seen by other members of the staff who agreed with the diagnosis.

CORNEAL OPACITY WITH MICROCORNEA

DR. MARIN AMAT presented a 5-month-old girl who, shortly after birth was treated with injections of Hepabismuth. She received 36 intramuscular injections twice weekly, and no results were obtained. The child's eyes were turned upward all the time, hiding the cornea under the upper lid, as is found in those born blind. She was given a subconjunctival placental injection (Filatov's method) in hope that it might stimulate the biologic development of the fetal cornea tissue.

RETINAL EDEMA

DR. MARIN AMAT presented a patient who showed a quadrangular zone of retinal edema between the macula and the papilla apparently due to a disturbance of the circulation. He thought the condition was due to a spasm of a cilioretinal vessel whose exit from the papilla at the border of the scleral opening was compromised and appeared thin and threadlike.

An examination of the patient showed, in addition to the edematous zone, a slight clouding of the retina in the upper half, the upper branch of the central artery of the retina was thin, almost threadlike. Perimetric examination showed a loss of vision in the lower half of the visual field, although central fixation was retained.

Treatment with vasodilating drugs (acetylcholine, vasil, eupaverine, nicotinic acid) prevented a spasm of the inferior branch of the central artery, which usually occurs. By using intramuscular injections of organic iodine, a satisfactory cure was obtained, the patient having a visual acuity of 1.00 (20/20) in the eye and only a slight peripheral reduction of the visual field in the lower part. However, there remained a slight pallor of the papilla and a slight reduction in the caliber of the arteries in the upper half of the retina as compared to those of the lower half. The favorable outcome of the case is shown by the visual field charts taken during the course of the disease. In addition to this result, which is worth while reporting, the case offered the unusual opportunity of following ophthalmoscopically the evolution of a retinal arterial spasm.

PTOSIS OPERATION

DR. MARIN AMAT showed a girl who was operated on for congenital ptosis of the upper lid by the procedure of Friedenwald and Guyton. The simplicity and effectiveness of this method deserve its widespread application (published in the AMERICAN JOURNAL OF OPHTHALMOLOGY, 31:411 (April) 1948).

EPIBULBAR EPITHELIOMA

DR. MARIN AMAT AND DR. MARIN ENCISO presented the case of a woman who, following the embedding of a foreign body in the cornea, developed a wartlike structure in the upper-outer portion of the corneal limbus. It was removed three times, but rapidly reformed. She entered the Provincial hospital of Madrid where the authors diagnosed the lesion as an epithelioma.

Operation consisted of complete extirpation of the neoplasm with treatment of the region of the implantation at the corneal limbus by diathermy and a conjunctival covering. Histopathologic examination showed the lesion to be a prickle-cell epithelioma, a type most refractory to radiotherapy. Four months after the operation there was no recurrence. Visual acuity was normal and the globe was not affected.

LEUKOSARCOMA OF IRIS

DR. MARIN AMAT AND DR. MARIN ENCISO presented the case of a 46-year-old

woman who had had a circumscribed lesion in the iris for a period of 10 years which gave her no trouble until the beginning of the year when she showed a hemorrhage in the anterior chamber. This was absorbed in a few days, but shortly thereafter there occurred a more extensive hemorrhage which alarmed the patient considerably. The examination showed a neoplasm, the size of a grain of rice, white and surrounded by many thick capillaries, and in addition a deposit of dark brown blood (the remains of the last hemorrhage) in the anterior chamber. The condition was diagnosed as leukosarcoma, and the treatment consisted of excision of a large section of the iris which contained the neoplasm. Histopathologic examination confirmed the clinical diagnosis of a leukosarcoma. The postoperative course was uneventful, and resulting vision was 20/20.

The authors then discussed the apparent rarity of a leukosarcoma in a pigmented organ like the iris, the slow evolution of the neoplasm, the uncertainty of the time period for the development of metastases in distant organs, and the great advantage of being able to preserve the eye and normal vision whenever possible.

Discussion. Dr. Carreras Matas said that this case was a typical example of a sarcoma of the iris which is curable by extirpation of the iris. More delay might have proved too late and the patient should be congratulated on having been treated so wisely and in time. That the lesion was a leukosarcoma is rather curious. One must remember, however, that, although it originated in a tissue very rich in melanophores, the melanoblasts in the adult eye are very scarce, being found almost exclusively at the corneal limbus.

RETINITIS PUNCTATA ALBESCENS

DR. B. CARRERAS MATAS referred to an observation of a patient with retinitis punctata albescens who, having had hemeralopia of a half hour's duration, began to notice at the age of 18 years absence of the dis-

turbance on rainy days although not consistently. This indicates a shortening of the time of adaptation and an evident improvement.

Discussion. Dr. Marin Amat said that the interesting thing about this affection were the points which this condition has in common with pigmentary degeneration of the retina and the points wherein the two conditions differ.

The points in common are: (1) Both are congenital, (2) appear in the first years of life, (3) are found in several members of the same family, and (4) the patients show difficulty of adaptation to low illumination.

The differences are (1) In the progress (pigmentary degeneration is always progressive, whereas retinitis punctata albescens very rarely increases), (2) the fundus shows completely opposite pictures (black spots in one and white spots in the other, with alteration in the retinal vessels and atrophy of the papilla in the advanced stages of retinitis pigmentosa), (3) alteration in the visual field in retinitis pigmentosa begins with a large annular scotoma with preservation of the peripheral and central fields and in retinitis punctata there is a concentric contraction.

Dr. Matas, in closing, said that the ophthalmoscopic pictures described by Japanese authors on hemeralopia due to dietary deficiencies are very suggestive. The observations of Dr. Tena Ibarre refer to the progressive form of the disease. But there certainly exist benign forms which tend to get better. Our patient is one of them.

PLASTIC SURGERY OF LID

DR. TENA IBARRE presented a case of blepharoplasty of the upper lid. The method of Fricke (tissue taken from the temple) and the method of Snydacker (taken from further parts) were used, and the result esthetically and functionally was perfect.

Translator.

ACTH IN MYASTHENIA GRAVIS

One of the functions of the editor of an ophthalmic journal is to bring to the attention of his readers discoveries in other fields of medicine that may be of significance in his specialty and to point out lines of investigation that may be fruitful in his field.

Since last May when the Mayo Clinic announced the spectacular results that had been procured by treating rheumatoid arthritis with Compound E, or cortisone, the medical world has been impressed, stimulated, and exhilarated. Ophthalmologists share in this excitement for ocular signs and symptoms, even blindness, are fre-

quently associated with rheumatoid arthritis and rheumatic fever. To cite some examples, phlyctenular conjunctivitis, scleritis, iritis, keratoconjunctivitis, scleromalacia perforans, Reiter's disease, Behçet's syndrome, and others.

Cortisone, prepared solely form bile acid, is difficult and expensive to produce and the quantity for experimental studies is restricted. The newer drug, adrenocorticotropic hormone, called ACTH at present, presumably stimulates the adrenal glands to secrete more cortisone. ACTH is an extract of the pituitary of hogs. It is said that about 200,000 hogs are required to produce half a

pound of the drug. It is, therefore, costly to produce and extraordinarily difficult to prepare. The clinical work that is necessary to prove the usefulness of this product cannot be done until an adequate supply is available.

The United States Public Health Service is attempting to discover new sources of supply, and has reason to believe that the African Strophanthus sarmentosus seed may provide more of the remedy. A joint expedition sponsored by the Public Health Service and the Department of Agriculture has been dispatched to Africa, Malaya, Liberia, and China to obtain specimens of various plants. The synthesis of the drug will require much effort and time. Thus, we see that the physicians in daily practice and their patients have a long wait ahead before an adequate supply of either cortisone or ACTH is available for daily use.

In the meantime, as is usual when any new and startling remedy is announced, the drug is being tried in conditions other than that for which it was first employed, in this case rheumatoid arthritis. Dr. Torda and Dr. Wolff report in the *Proceedings of the Society for Experimental Biology and Medicine* (71:432, 1949) on the effects of adrenocorticotropic hormone on neuromuscular function in patients with myasthenia gravis.

It was administered by these investigators to patients with myasthenia gravis mainly on the basis of the following observations and inferences: (1) The immediate cause of the symptoms of myasthenia gravis is a decrease of acetylcholine synthesis; (2) administration of ACTH increased acetylcholine synthesis in vivo; (3) increase of the lymphatic tissue, round-cell infiltration of various organs, mainly striated muscle, and hyperfunctioning thymus have been found in patients with myasthenia gravis (studies have shown that one of the sources of the substances that inhibit acetylcholine synthesis is the thymus—administration of ACTH induces reduction of the mass

of the thymus and the lymphatic tissue); (4) removal of the pituitary gland in rats induces changes in the electromyogram that closely resemble the abnormalities noted in patients with myasthenia gravis; and (5) the pituitary gland of several patients who died of myasthenia gravis showed accumulation of an eosinophilic colloid material suggesting altered function of the gland.

Torda and Wolff administered 400 mg. adrenocorticotropic hormone in amounts of 20 mg. every six hours to five patients moderately to severely ill with myasthenia gravis. "Changes that may indicate the beginning of an incomplete remission occurred after completion of the injections. These changes consisted of decrease of the symptoms and outward manifestations of muscle dysfunction, disappearance of the abnormalities noted in the electromyogram, increased work performance in the ergograph, and increase to normal of the ability of serum to support acetylcholine synthesis. The incomplete remission appears to be long standing."

The authors of the report exhibit a praiseworthy restraint in reporting their findings. Those who take the trouble to read the paper will be impressed with the high scientific caliber of their work and presentation, quite different from many reports of the results obtained from other "biogenic stimulators."

One can foresee in the near future the employment of ACTH in all sorts of chronic and hitherto unexplained maladies, even retinitis pigmentosa, for example. This is praiseworthy and necessary; but it is to be hoped that, like those of Torda and Wolff, such clinical experiments will be conducted on the highest scientific plane and the results modestly and properly presented.

Derrick Vail.

————————

LIGHTING FOR TRAFFIC SAFETY

Visual impressions register more slowly as the level of illumination drops. Consequently, motor accidents at night entail a

severer toll in deaths, injuries, and property damage since the driver is allotted less time and space to avoid contact or reduce the force of impact. Per accident at night the bodily injuries are more serious and the property damage 50 percent higher than in daytime.

Night driving is being facilitated by more efficient headlights and more adequate illumination on streets and highways. In daylight, an obstacle is distinguished by the detail revealed by its reflected light. Enough artificial light to allow such discernment is not generally practicable nor indeed necessary except for crowded business areas.

Satisfactory visibility is obtained if the background is brighter than the object (silhouette discernment), or if the object is brighter than the background (reverse silhouette). Adequate pavement brightness permits all important pavement details to be seen and makes silhouette discernment effective.

Pavement brightness depends on the illumination and the pavement reflectance. The diffuse reflection factor of a 10-year-old concrete pavement is 22 percent; of similar asphalt and brick pavements, 7 percent. The more-reflecting surface gives a greater distance of road visibility. Pedestrians are the most important of obstacles, and the reflectance of their clothing ranges from 2 to 15 percent, the average for men's clothing being 5 percent.

When electric lighting was first applied to headlamps in 1914, the single all-purpose beam provided a compromise between road illumination and glare. The dual beam became necessary as operating speeds increased, and was introduced in 1930. The driving beam of 50,000 candle power allowed seeing at a sufficient distance to stop a car travelling 45 miles per hour in about 200 feet. This apparently fulfilled the requirements, since the motorist's line of sight usually centers at a point approximately 200 feet ahead of the car. But, because of the

time factor in vision, decreased visibility accompanied further speed. For each increment of one mile per hour in speed, a driver perceives an unexpected obstacle at two feet less distance.

Since 1940, the driving beam produced by a pair of headlights has been increased to 75,000 candle power. The depressed beam for the reduction of glare now directs more light to the right edge of the road which aids vision during the approach of another car. The reflector, filament, and lens are aligned and hermetically sealed during manufacture to insure perfect and permanent focus. The "sealed beam lamps," now in universal use, maintain almost their initial output throughout the life of the car. When driving in dense fog, the depressed beam must be used as the layer of lighted fog between the roadway and the driver's eyes is then thinner and so causes less interference with seeing.

On city streets and on roads with high traffic density, headlamp lighting alone is insufficient. Fixed lighting is necessary which should give a minimum value per square foot of street surface of 0.4 to 1.2 foot-candles, according to the density of pedestrian and vehicular traffic. Controlled light direction is obtained by the reflector-type pendant luminaire. Glare is avoided by raising the lamps high above the street level. The glare effect at the height of 20 feet is double that at 30 feet. The entrances of long tunnels must have supplementary lighting for daytime operation to avoid a too abrupt light change. At 25 feet from the tunnel entrance, the illumination should be 100 foot-candles; at 100 ft., 25 foot-candles.

With the same amount of light similarly distributed, equal visibility is produced by sodium-vapor, mercury-vapor, and filament lamps.

The filament lamp is best adapted for general use. It produces light of pleasing color and is available in a wide variety of sizes. Globes of clear rippled glass are

preferable because of the low light absorption.

Mercury-vapor lamps for street lighting are made in 250- and 500-watt sizes. Although costly to install, their high efficiency makes maintenance economical. The color contrasts well with the display lighting of business districts. In Los Angeles, the obsolescent arc lamps on Broadway were recently replaced with 16,000 lumen mercury-vapor units. The new lighting gives the street two foot-candles as compared with 0.31 foot-candles of the old system at 20 percent of the operating cost.

Sodium-vapor lamps are only in 10,000 lumen units. This attention-getting light is especially good for underpasses, bridges, railroad crossings, sharp curves, and dangerous intersections. The yellow light gives complexions an unnatural appearance and hence is not desirable for city streets. Sodium-vapor lamps are much more costly than equivalent filament globes but give nearly three times as much light per watt.

City lighting systems were originally designed for protection against robbery and other crimes; lighting to enhance business areas followed; but only lately has lighting for traffic safety become a goal. Since 1910, the expenditures for street lighting have gone up but 60 percent while the speed of cars has doubled and the traffic density has increased fivefold. The main traffic arteries in towns and cities, although one tenth of the total street mileage, account for half of all urban fatalities. The National Safety Council asserts that 35 percent of all night traffic accidents are traceable to inadequate lighting. The overall ratio of night to day fatalities has increased from 1.0, in 1930, to 1.4, at present, due to the lag of night lighting in relation to the growth of traffic.

In Chicago, a 1940 study showed that 35 percent of the total traffic fatalities occurred in 4.4 percent of the total street milage, and that more than 62 percent of the fatalities happened at night. After five dangerous

insections were provided with improved lighting, the total night accident rate dropped 37 percent. In Detroit in 1936, the average illumination on the main thoroughfares was 0.2 foot-candles. When this was increased to 1.2 foot-candles the ratio of night to day fatalities on these streets decreased from 6.9 to 1.4. Since November 1, 1946, when Indianapolis revised its prewar lighting, the annual night accidents on a typical busy street fell from 23 to 14. In Los Angeles, the improved street lighting inaugurated in 1947 reduced night pedestrian fatalities by 33 percent over the previous year. A decade of good lighting in Hartford, Connecticut, showed, in comparison with the previous decade, a reduction of 76 percent in night fatalities, 78 percent in pedestrian injuries, and 58 percent in all types of accident.

During the depression of 1932, Detroit reduced its lighting 35 percent, and, as a consequence, the proportion of night to day fatalities doubled. The cost of caring for the victims of traffic accidents more than exceeded the savings. In the dim-out of 1942 the ratio of night to day fatalities in New York City and Long Beach, California, rose from 1.33 to 2.15. In Connecticut the night accident rate that year increased 35 percent.

Automobile accidents are brought about by a combination of circumstances, and the removal of one factor often results in avoiding the accident. The more certain seeing provided by good lighting reduces the accident quota previously attributed to inattention, carelessness, fatigue, speeding, or drunkenness. At minimum visibility drivers reacted to an unexpected obstacle at 20 to 80 percent of the distance noted when warned of its presence. Hence a safety factor of 2 to 5 is required for the variation in driver attention alone. In reading with 10 foot-candles, as compared with the minimum illumination necessary (0.1 foot-candles), the safety factor is 100. In instruction signs on the road the color combinations chosen should be those seen best under

minimal illumination, such as black on aluminum, white on dark green, black on yellow, or black on white.

Accidents preventable by good lighting cost the nation annually 10,000 lives and $187,000,000. Modernized lighting is expensive, but it can be had at half this dollar loss and would, moreover, expedite pedestrian and vehicular traffic, increase property values, reduce crime, and promote civic pride.

James E. Lebensohn.

CORRESPONDENCE

Professor Meller's Birthday

Editor,
American Journal of Ophthalmology:

Many of the readers of the Journal will be interested to hear that Prof. Joseph Meller's 75th birthday will be celebrated at the University of Vienna on October 22, 1949. Somewhat older than when seen last by most of his American friends, but unbroken in body or spirit by the trials and tribulations of the last decade, Professor Meller will receive the international group of well-wishers and congratulators with the multilingual warmth and sparkling wit for which he is so widely known.

Joseph Meller was born in the town of Stein on the Danube on October 22, 1874, attended primary and middle school in the nearby town of Krems, and university and medical school in Vienna. During his undergraduate years, he showed special interest in anatomy and internal medicine.

Just when and how Meller's mind turned toward ophthalmology as a vocation is not known to me. The fact is that Meller's ophthalmic career started in 1898 when he became a resident at the Second University Eye Clinic or, as everybody then knew it, the Fuchs Clinic in Vienna.

Right from the beginning, he and ophthalmology got along well. He ascended the academic ladder with remarkable rapidity. In 1905, he had advanced to the position of first assistant; in 1912, to that of associate professor. In 1915, he was appointed to the Chair of Ophthalmology at the University of Innsbruck, from where he returned to Vienna in 1918 when, through one of the last decisions of the Austrian Emperor, he was appointed professor of ophthalmology and director of the First Eye Clinic at the University of Vienna.

After having reached ophthalmic maturity and fame in the heydays of the Austrian Empire and of the Viennese Medical School, Meller now had to shoulder the responsibility for carrying on under most adverse, most discouraging conditions, which—with brief intermissions—prevailed up to the time of his dismissal by the Ministry of Science and Education of the German Reich in 1944.

As early as 1939, one year after the "Anschluss," and again in 1942, Meller had submitted his resignation, but was prevailed upon by the Executive Faculty to continue at his post. His frankness in academic matters had led to a number of disagreements with the "Authorities in Berlin" which in a letter dated May 10, 1944, finally relieved him of all his academic duties "in the interest of the younger academic generation."

After 25 years of leadership under the most varied but never really favorable conditions, Meller retired to literary work and private practice in which he is still actively engaged.

Meller's scientific accomplishments are too well known to require more than brief mention here. There is no field in ophthalmology to which he has not made important contributions. His list of publications, 124 up to date, clearly reveals pathology as his main approach to ophthalmic problems, and as the recommended and actually practiced basis of his clinical thinking and acting.

Of his many fields of special attainments, his work on the tuberculous etiology of endogenous uveitis is probably most signifi-

cant. In Meller's own classification of ophthalmologists, he undoubtedly belongs to the small group that "keeps on working indefatigably in order to produce more and newer evidence in favor of the tuberculous etiology of endogenous uveitis."

In the United States, Meller is probably best known as the author of his textbook on *Ophthalmic Surgery,* the first edition of which was published in English in 1908. During a period of 40 years, seven editions of this text have been printed and avidly absorbed by ophthalmic readers all over the world. The success of this book, in my humble opinion, is due to Meller's mastery of the art of ophthalmic surgery as well as to his mastery of the art of clear, logical ophthalmic thinking, speaking, and writing. Of both of these arts he has given most generously. Three fourths of all the surgical patients of the clinics under Meller's direction have had the opportunity and benefit of his own, personal, surgical skill.

His mastery of the art of clear logical thinking accounts for his success as a teacher. His great gift of making the principles of ophthalmology attractive and fascinating to the undergraduate student is matched by a much-envied facility in presenting transcendental ophthalmology to very learned audiences.

During 44 years of academic activity, Meller has raised a large ophthalmic family, the American members of which, in the simple fashion of this country, will want to add "many happy returns" to the wishes of those who will be fortunate enough to attend the birthday celebration personally.

(Signed) Peter C. Kronfeld,
Chicago, Illinois.

BOOK REVIEWS

SURGERY OF THE EYE. By Meyer Wiener, M.D. New York, Grune & Stratton, 1949, second edition. 392 pages, 425 figures, index. Price, $12.00.

The first edition of Dr. Wiener's popular book on ophthalmic surgery and a second printing of it were quickly absorbed. The new publishers have performed a useful service in bringing out this second edition.

It has been revised and some parts have been rewritten by the author, who has brought up to date the advances in this art that have occurred in the last 10 years. This includes cataract sutures, goniotomy, and orbital implants. The author's method of corneal transplantation by means of a specially constructed punch is described and promoted as a tried and proven measure.

Old readers who are familiar with the first edition will recognize the arrangement of illustrations and text as old friends. Newcomers will find much of interest, value, and instruction. The views expressed, while generally universally held, are primarily based upon the experience of a great ophthalmic surgeon.

Derrick Vail.

CLINICAL ORTHOPTICS: DIAGNOSIS AND TREATMENT. By Mary Everist Kramer, Supervisor, The Orthoptic Department, The George Washington University Hospital, Washington, D.C. Edited by Ernest A. W. Sheppard, M.D., Professor of Ophthalmology, and Louise Wells Kramer, Certified Ophthalmic Technician. St. Louis, The C. V. Mosby Company, 1949, 475 pages, 147 illustrations, cloth bound. Price, $8.00.

The discussions of orthoptic training, strabismus, fusion, amblyopia ex anopsia, abnormal retinal correspondence, convergent and divergent strabismus, the vertical deviations, and the heterophorias are taken up in order. The author with the assistance of her co-writers presents an excellent resume of the anatomy, the visual pathways and oculomotor system, physiology, and optics for the use of an associate in the ophthalmic field.

At the end of each chapter are questions

relevant to the material presented and a list of references.

The different types of instruments including the major amblyoscopes and the other equipment available for making an examination of the ocular muscle balance are given and the mechanics illustrated.

The chapter on surgery by Dr. Ernest A. W. Sheppard emphasizes the importance of a complete diagnosis before surgery is outlined. The discussion of reading disabilities completes the presentation of orthoptics, as the hope of many parents of these children is that ocular training will improve reading ability. Miss Kramer discusses the complex problem and gives a list of references that will help the physician, as well as the parents, when confronted with reading problems in children.

                         Beulah Cushman.

LE MENINGO-ENDOCRANIOSI IN OFTAL-MOLOGIA. By Alfio Rubino. Bologna, 1949. 93 pages, 25 figures, bibliography.

In this monographic treatment of chronic arachnoiditis, the author indicates the importance of an understanding of the syndrome for many branches of medicine—neurology, endocrinology, and radiology, no less than ophthalmology..

A short review of the history of our knowledge of the lesion goes back to Morgagni. The author then discusses the etiology and pathogenesis and the relation to lesions in contiguous tissues. After a discussion of the general symptoms and radiologic signs, the eye manifestations and their significance are described and discussed in detail.

For example, the author points out the significance for topographic diagnosis of his "small chiasmatic syndrome" which consists of edema of the optic disc with passive hyperemia of the central retinal veins and signs of arterial and venous hypertension combined with a bitemporal upper quadrant hemi-anopia for color. In another chapter the relationship of the lesions to classic opticochiasmatic arachnoiditis is discussed at length. There is possibly a relationship to the Laurence-Moon-Biedl syndrome and to Leber's optic atrophy. In the concluding chapter some therapeutic suggestions are made.

                         F. H. Haessler.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF NEW ZEALAND (supplement to the New Zealand Medical Journal. Wellington, New Zealand, British Medical Association (New Zealand branch), 1948. Pamphlet form, paper covers, 74 pages.

Herein are published the papers presented at the second conference of the Ophthalmological Society, held at Dunedin, February, 1948. In addition to other papers mentioned below, the report is outstanding by reason of the presidential address, by Rowland P. Wilson, on "Some conjunctival affections." Dr. Wilson is well known for his 19 years of work in Egypt, the reports of which used to appear in the annual transactions of the Giza Institute of Egypt. His presidential address before the New Zealand society is chiefly occupied by an excellent review of the present status of knowledge concerning trachoma, although it deals also with various aspects of bacterial conjunctivitis, follicular conjunctivitis, spring catarrh, and allergic conjunctivitis. (Trachoma is approximately absent from New Zealand, except perhaps among the Maoris of the North Island.)

It is emphasized that what has been historically referred to as "military ophthalmia" or "ophthalmia egyptica," on account of its great incidence among the French and British armies during the Napoleonic campaign of 1798-99 in Egypt, was not an uncomplicated trachoma but a combination of trachoma with various forms of acute bacterial conjunctivitis, the greater part of the affected soldiers being blinded by acute

gonococcal conjunctivitis. Actually, not more than one percent of the blindness in Egypt is due to trachoma, although at least 95 percent of the indigenous population of Egypt is infected by that disease. "Trachoma is of low infectivity and only flourishes in the presence of bad hygienic conditions, carelessness, and apathy." "Unfortunately one of the principal obstacles in the way of further progress in the investigation of the disease is the fact that there is really no satisfactory experimental animal other than man."

Wilson's address is accompanied by 27 splendid illustrations, beautifully reproduced, most of them photomicrographs, and dealing with trachoma, folliculosis, and spring catarrh.

The other papers included in the annual report are: by J. B. Hamilton of Tasmania on the prognosis of sarcoma of the choroid (geneological trees); by W. A. Fairclough on cataract in dystrophia myotonica; by Graeme Talbot on pterygium; by W. C. Burns on herpes ophthalmicus associated with chicken-pox; by C. A. Pittar on late results of successful operation for detached retina; by W. J. Hope-Robertson on the prevention of industrial eye accidents; by W. H. Simpson on penetrating wounds of the eye; by W. A. Fairclough on contact lenses; by L. S. Talbot on congenital dislocation of the lens; and by J. S. Munro on dislocation of the crystalline lens.

The New Zealand Society has 40 members, comprising practically all the ophthalmologists in the country.

W. H. Crisp.

HISTOLOGY AND HISTOPATHOLOGY OF THE EYE AND ITS ADNEXA. By I. G. Sommers, M.D., Los Angeles, California. New York, Grune & Stratton, 1949. Clothbound, 764 pages. Price, $12.00.

The book is divided into three parts. The first 53 pages are devoted to very brief discussions of the normal histology, embryology, and senescence of the eye.

The second part entitled "General pathology in relation to the eye" should stimulate the interest in ocular histopathology of the beginner who often finds this subject dry unless it is correlated with more familiar clinical and pathologic knowledge.

The third part deals with the specific histopathology of the ocular tissues. It contains a wealth of informative material but suffers acutely from the paucity of illustrations. Greater brevity in stating the essential pathologic findings of each condition in lieu of pages of flowing descriptions without highlights, would greatly facilitate, particularly for the beginner, the creation, at least, of mental pictures.

It is also disappointing that the author did not avail himself of more modern terminology and classifications, as for instance in the discussions of tumors and the glaucomas.

The book is difficult to read because of the innumerable "Germanisms" in expressions and grammar, which not only mar the elegance of style but also detract from the clarity of statements, making them not infrequently ambiguous.

The most valuable part of the book, at least in this reviewer's opinion, is the short digest of source material, and the pertinent bibliography which follows each chapter. Although of necessity incomplete, it should promote collateral reading and acquaint the reader, without confusing him, with various divergent opinions expressed in the literature.

Bertha A. Klien.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Fischer, Franz. **Embryonic properties of lens fibers.** Klin. Monatsbl. f. Augenh. 114:202-205, 1949.

In larvae of salamandra maculosa in which the lens had been removed 70 to 120 days before histologic examination, the author found that primary lens fibers can grow unusually long and are only inhibited in this growth by the anterior wall of the lenticular vesicle. The epithelial wall of this vesicle and the pressure within it are the definitive factors in the normal development of the lens fibers. The developing fibers have the property of imitating the form of a lens without the influence of an external factor. (3 figures, references.)

Max Hirschfelder.

Vetter, Joachim. **Peculiar pigmentation in optic nerves and surrounding tissues of the globe in animals.** Klin. Monatsbl. f. Augenh. 114:214-218, 1949.

The pigmentation of the region within and around the lamina cribrosa is very variable in different groups of animals as well as within the same group. The author examined the eyes of forty mammals and describes especially the pigmentation in camels (very fine pigmentation within the lamina mesh), in hyenas (coarse pigment) and in wapitis which show an unusual amount of pigment within the optic nerve along its sheats. This pigment is not related to the one found in the pigment layer of the retina. (3 figures, references.)

Max Hirschfelder.

2

GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Zollinger, R. **The occurrence of mast cells in iris and ciliary body.** Ophthalmologica 117:249-252, April-May, 1949.

True mast cells occur in pathologic sections of the uvea of chronically inflammed human eyes. In small numbers mast cells can be found in many ocular conditions and in similar numbers in the aqueous.

Peter C. Kronfeld.

3

VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Goldmann, H. **Do the aqueous veins contain aqueous?** Ophthalmologica 117: 240-243, April-May, 1949.

Goldmann reports accurate fluorescein determinations made in blood and aqueous by means of an optical method with an accuracy of ±5.5 percent. With this method he found the fluorescein concentration of the plasma to be at least a hundred times greater than that of the aqueous during the first hour following the intravenous injection of fluorescein. The absence of fluorescence under these conditions proves conclusively that the aqueous veins do not contain blood plasma.

Peter C. Kronfeld.

Michiels, J. **Experimental study on the formation of the aqueous humor.** Ophthalmologica Supplement No. 34, 1949.

The static and dynamic chemistry of the aqueous is reviewed rather thoroughly. No clear concept of the function of the blood-aqueous barrier can be derived from the experimental data which are now available. The author has studied the appearance in and disappearance from the aqueous of gum arabic which he injected intravenously into rabbits in a solution of the same osmotic pressure and viscosity as that of blood. Between 50 and 100 cc. of the gum solution were injected at the rate of about 2 cc. per minute. Gum arabic entered the aqueous in measurable quantities, together with an abnormal amount of blood protein. Just as in studies by other authors, the intravenous injection of gum arabic was found to alter the permeability of the blood-aqueous barrier. It is unlikely that the gum itself exerted any chemical or toxic effect on the capillary wall. The colloidal state of the blood was changed very profoundly by the addition of the gum. Probably this changed physical status affected the capillary wall. The gum disappeared from the aqueous slowly and without having been broken down into smaller molecules since the rabbit does not possess any enzymes that break down gum arabic. No important conclu-

sions concerning the elaboration of normal aqueous can be drawn from work of this kind.　　Peter C. Kronfeld.

Schenk, Fritz. **Pharmacological effects upon the ocular tension of the rabbit.** Ophthalmologica 118:42-65, July, 1949.

The effects upon the ocular tension of the drugs most commonly used in ophthalmology were studied on rabbits under urethane anesthesia. Fairly consistent fluctuations were observed after the instillation of atropine, hyoscyamine and scopolamine. An initial rise of from 1.5 to 4.5 mm. was followed by a drop of from 6.5 to 8 mm. The original level was reached after 3 to 4 hours. In 2 out of 26 rabbits the drop in tension was followed or superseded by a marked secondary rise. The instillation of cocaine caused fluctuations similar to those observed after atropine. Indifferent results were obtained after the intravenous injection of acetylcholine, methylene blue, caffeine and histidine. Ergotamine caused a slight drop in tension. In general, the administration of a large variety of drugs produced either no appreciable effects or a slight to moderate drop in tension. Whatever the experimental procedure is, the normal eye of the rabbit is more apt to respond with a drop than with a rise in tension. In a small number of rabbits the response is very different from that of the overwhelming majority. This exceptional behavior may be an expression of vasomotor or vegetative lability.

Peter C. Kronfeld.

4
PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Beach, S. J. **"Myopia cures."** Tr. Am. Ophth. Soc. 46:284-294, 1948.

The author discusses some evidence consistent with the unorthodox theory that improvement in vision in nearsighted persons which follows sight train-

ing exercises may in some instances be due to a genuine reduction of the myopia. The feature of sight training courses that keeps the devotees faithful is the flashes of distinct vision they elicit. As it frequently is monocular and shifts from one eye to the other it cannot be ascribed to improved interpretation of blurred images on the cerebral level. It seems to be a development of the squinting used by myopes. Use of akinesis of the orbicularis and retrobulbar akinesis of the extraocular muscles might give a clue to whether pressure is exerted by the orbicularis or the extrinsic musculature.

David Harrington.

Blum, J. D. **The tolerance for contact lenses.** Ophthalmologica 117:214-217, April-May, 1949.

A questionnaire was sent to fifty consecutive patients who had received molded plastic contact lenses and 86 percent reported that they are wearing their lenses for an average of nine hours every day.   Peter C. Kronfeld.

Dufour, R. **Plastic contact lenses. Preliminary report.** Ophthalmologica 117: 207-211, April-May, 1949.

This report from the University Eye Clinic of Lausanne deals with the results obtained with plastic molded contact lenses in 60 patients with varying ocular conditions. The lenses are constructed to admit a capillary layer of tear fluid between cornea and contact lens, either through an area of clearance nasally and below or through multiple channels in the scleral portion of the lens. Sixty percent of the patients are satisfied with the lenses and wear them regularly. In several cases of qualified success or failure, the fitting process has not been completed. One retinal detachment occurred coincidentally during the fitting process. The author's conclusions and experiences

do not differ significantly from those of the American ophthalmologists.

Peter C. Kronfeld.

Handmann, M. **Myopia after inflammatory diseases in the anterior part of the bulbus.** Klin. Monatsbl. f. Augenh. 114:224-233, 1949.

Factors of inheritance are the main cause in myopia. However, there are instances of myopia which cannot be ascribed to inheritance. The author describes the case histories of 14 patients who had unilateral myopia as a late result of dendritic, parenchymatous and eczematous keratitis. Amblyopia was frequently associated with the nearsightedness which developed over the course of many years. The author believes that inflammatory processes of the cornea may influence the metabolism, growth and tissue stability of the sclera as a whole. (References.)   Max Hirschfelder.

Knuesel, O. **Further experiences with contact lenses.** Ophthalmologica 117:212-213, April-May, 1949.

The author stresses the nonspherical surface of most human eyes. He measures the curvature of the sclera in several meridians and constructs the contact lens on the basis of these measurements. Accurate fitting of the scleral portions is the most important factor in the success of a contact lens. Corneal edema is usually due to one or two tight areas or a very tight fit of the entire scleral portion. The composition of the contact lens solution is of no significance. One patient is equally comfortable with well water or apple cider.   Peter C. Kronfeld.

Lancaster, W. B. **Some secondary subjective effects produced by prisms.** Tr. Am. Ophth. Soc. 46:262-283, 1948.

The various optical distortions produced by prisms can be explained on the

basis of the obliquity of incidence of the rays in two significant planes, the base-apex plane 'and a horizontal plane. The author's explanation of the obliquity is offered as a new contribution to the subject. When a prism is cut at right angles to the base and to the sides, the cross section is a triangle of minimum base and minimum apical angle. When it is cut obliquely, but still at right angle to the base, the triangular cross section has a longer base, a larger apical angle and more power to cause deviation.

DIAGNOSIS AND THERAPY

Alden, H. S., Jones, J. W., and Rankin, J. Roentgen-ray treatment of the eye. Arch. Derm. and Syph. 59:430-434, April, 1949.

For 15 years the authors have used roentgen rays on 300 patients with corneal ulcer. A method is described whereby the cornea can be prepared and 160r per minute applied to it. The average dose used is 70 to 80r at weekly intervals for five treatments. Tissues that receive less than 300r usually recover while tissues that receive 1500r or more do not recover from damage caused by the rays. Of 159 patients treated before 1943 the average dose was 252r. Over 60 percent of these have been examined with the slit lamp and show no changes in the lense. One patient who had received other X-ray therapy for a resistent blepharitis had some slight lenticular opacities.

H. C. Weinberg.

Amsler, M., and Verrey, F. Injections of pencillin and adrenalin into the anterior chamber. Ophthalmologica 117: 243-246, April-May, 1949.

Penicillin, 300 to 400 units dissolved in 0.2 cc. of 2-percent procaine, plus a small amount of adrenalin is injected into the anterior chamber immediately after most of the contents have been withdrawn by means of a hypodermic needle and syringe in cases of serpentic ulcer, endogenous acute and chronic uveitis, perforating injuries, and intraocular foreign bodies. Results were on the whole good, at times almost miraculous, and other times nil. Injected into the anterior chamber, epinephrine is a powerful mydriatic.

Peter C. Kronfeld.

Badtke, G. Treatment of the eye with supersonic stimuli. Klin. Monatsbl. f. Augenh. 114:193-196, 1949.

Space and time difference of a wave have the physical effect of a massage of cells or cell groups. Local rise in temperature and stimulus of diffusion and penetration of fluids follow supersonic treatment. Therapeutic doses are too weak to damage the tissues by rupture and hemorrhage. The therapeutic dosage ranges up to 3.0 Watt per $\frac{1}{2}$ cm.^{2} Two stubborn cases of vitreous opacities after intraocular hemorrhage showed improvement after treatment with the ultrasonator and an incompletely absorbed chalazion responded to treatment. Experiments with rabbits eyes failed to reveal any damage to the tissues.

Max Hirschfelder.

Balcet, C. The use of novocaine in oil in ophthalmic practice. Rassegna ital. d'ottal. 18:44-47, Jan.-Feb., 1949.

Two-percent novocaine in almond oil has great advantages over the use of the aqueous solutions. The results of injection are practically uniform in effect. Anesthesia of the skin begins almost immediately and persists for 24 to 36 hours. Akinesia of the orbicularis appears within two minutes and lasts for six to eight days. The edema is slight and remains for only 24 to 36 hours. There are no subjective or objective disturbances and no tendency to produce ptosis or ectropion.

Retrobulbar injection of the oily solution results in more prolonged anesthesia and was used in cataract extractions and filtering operations for glaucoma. There is a striking difference in the action of the oleous solution on motor nerve fibers and sensory. The former are more profoundly and longer effected.   Eugene M. Blake. ·

Dupont, M. **The signs of syphilis or hereditary syphilis.** Ann. d'ocul. 182:295-300, April, 1949.

The clinical signs of acquired and congenital syphilis are compared with those of tuberculosis to facilitate more accurate ophthalmologic differential diagnosis. A familiarity with the extraocular evidences of syphilis is often of great value in differentiating ocular syphilis and tuberculosis.   Chas. A. Bahn.

Gát, L. **The technique of evisceration.** Ophthalmologica 117:343-346, June, 1949.

The evisceration of the globe has not been more widely accepted because of the danger of sympathetic ophthalmia and the slow and rather painful convalescence. The author removes the cornea completely by means of scissors and the ocular contents by means of a curette. The cavity is packed for two to five minutes to obtain complete hemostasis and is then thoroughly inspected for remnants of uveal tissue. After the internal surface of the sclera has been found to be perfectly clean and dry the cavity is filled with two or three grams of ultraseptyl, a sulfonamide, and the anterior opening is closed with interrupted sutures. Chemosis usually lasts less than four days.   Peter C. Kronfeld.

Goldmann, H. **Biomicroscopic findings in the chamber angle and in the eyeground.** Ophthalmologica 117:253-258, April-May, 1949.

The author describes and demonstrates in beautiful drawings some unusual

gonioscopic findings. His contact lens can be used to a great advantage in the study of fundus lesions. The important question whether small lesions are located in the outer retinal layers or in the lamina vitrea can be decided by slit lamp examination through Goldmann's contact lens.   Peter C. Kronfeld.

Morano, M., and Franchi, E. **Plesioroentgen therapy of ocular diseases.** Ophthalmologica 118:30-41, July, 1949.

The term plesio-roentgen therapy implies a special form of X-ray therapy. It is essentially a low voltage contact method in the development of which Chaoul has played an important part. The X-ray tube which is used in this work is designed by and named after him. In this paper beneficial results from this form of radiation are reported in tuberculous uveitis, localized, solitary chorioretinitis, deep keratitis and in some corneal ulcers. The doses were calculated to produce a series of biological effects which cause an increase of the vital power of the affected ocular tissues with following accelerations of the natural recovery process. Special care was taken to get a localized X-ray effect within the diseased tissue and a minimum of undesirable stray effect.   Peter C. Kronfeld.

6

OCULAR MOTILITY

Fink, W. H. **The surgical anatomy of the superior oblique muscle.** Tr. Am. Ophth. Soc. 46:154-184, 1948.

The superior oblique muscle, the trochlea, the reflected tendon and the insertion and such adjacent structures as the septum orbitale, the levator muscle, the superior rectus muscle, the nerves and blood vessels, and the various fascial membranes are described from the viewpoint of both the anatomist and the surgeon. Surgical procedures are limited to the re-

flected tendon and its insertion. Approaches to this area are discussed.

David Harrington.

Key, S. N., **Orthoptics without instruments.** Texas State J. Med. 45:146-148, March, 1949.

Two methods are described as supplemental to, or in place of the usual orthoptic training, a red filter which can be reduced in density, and bar framing exercises. Donald T. Hughson.

Pascal, J. I. **A static and dynamic muscle scheme.** Opthalmologica 117:217-221, April-May, 1949.

To facilitate the study of ocular muscle disorders, Pascal has devised a scheme in which the extraocular muscles are placed at the midpoints of the sides of a hexagon which is thought to be located in front of each eye. Proceeding clockwise from the 9-o'clock position, the arrangement of the muscles of the right eye on its hexagon is as follows: lateral rectus, superior rectus, inferior oblique, medial rectus, superior oblique, inferior rectus. The arrangement of the muscles of the left eye within its hexagon is the exact mirror image of that of the right eye. Such a scheme illustrates a great many physiologic as well as pathologic phenomena of ocular motility. Peter C. Kronfeld.

CONJUNCTIVA, CORNEA, SCLERA

Castroviejo, R. **Keratoplasty for the treatment of keratoconus.** Tr. Am. Ophth. Soc. 46:127-153, 1948.

From a thorough review of the literature on the surgical treatment of keratoconus and his own experience, the author concludes that the partial penetrating type of keratoplasty is the treatment of choice for advanced keratoconus. The preoperative study, technical details and minutiae which must be observed at the

time of operation, methods of suturing the graft and postoperative care are described, and the prevention of anterior synechia and their treatment when they occur, retransplantation after clouding of the graft, and use of radiation in the prevention of vascularization are discussed. (Photographs and drawings.)

David Harrington.

Heinsius, Ernest. **Involvement of the cornea in agranulocytosis.** Ophthalmologica 118:69-75, July, 1949.

The author reports a case of a severe, ulcerative, rapidly-progressive keratitis which for six days had been treated very inadequately at the patient's home. Most of the cornea was involved and a hypopyon filled more than the lower third of the chamber. During the first five days in the hospital the treatment consisted of atropine instillations, yellow oxide of mercury and optochine locally, and milk injections intramuscularly. Under this regime the corneal process became worse. Five days later penicillin treatment was started locally and systemically, and two days later a conjunctival flap was placed over the cornea. The corneal process began to regress but the patient's general condition was unsatisfactory and agranulocytosis was found which responded well to blood transfusions. The patient made a slow recovery. At the time of discharge the affected eye could count fingers at a short distance. The agranulocytosis might have been brought on by some analgesic such as amidopyrine, which the patient received early, but the author suggests that the patient had agranulocytosis from the beginning and that the corneal ulcer was just one of its manifestations.

Peter C. Kronfeld.

Jirman, J. **Physiologic treatment of certain corneal lesions.** Ann. d'ocul. 182:449-454, June, 1949.

Corneal healing depends largely upon the diffusion and osmosis of its nutritive substances. In the treatment of corneal burns and neuroparalytic keratitis the author had used amino acids, including a 2-percent glycocol solution and hemolized blood serum locally with intramuscular injections of 2 to 4 cc. histadine. He also uses antibiotics and irrigates with Ringer's solution. Six severe cases of corneal burns from acetone, potassium hydrate, hot iron, lime and methylene blue were treated by this method, and three of neuroparalytic keratitis. The results recorded were surprisingly favorable. There was very little loss of vision.
Chas. A. Bahn.

Paufique, M. and Etienne, R. **The conjunctival-ganglion syndrome of Parinaud.** Ann. d'ocul. 182:455-460, June, 1949.

The case reported was the result of infection with blastomyces in a 32-year-old woman. The intradermal reaction of a lysate of Rodo turula was strongly positive and she had an eosinophilia of 15 percent. Potassium iodide was administered by mouth, but did not prevent gland suppuration. Chas. A. Bahn.

Stein, A. **The therapy of serpentic ulcer.** Ophthalmologica 117:227-230, April-May, 1949.

Maintenance of a high local concentration of antibiotics is essential in the treatment of serpentic ulcers. The author reports favorable results with penicillin baths applied to the cornea for as long as six hours by means of a rubber eye cup with adjustable rim. The penicillin concentration of the bath varies from 2,000 to 4,000 Oxford units per cc. of fluid. In severe cases these baths are administered day and night with only short rest periods every six hours. A similar eye cup is used for iontophoresis. In Switzerland serpentic ulcers are ap-

parently still fairly common and are caused by pneumococci or staphylococci.
Peter C. Kronfeld.

Varley, R., and Kletz, T. **A case of Kaposi's varicelliform eruption (systemic herpes simplex) with dendritic ulceration of the cornea.** Brit. J. Derm. and Syph. 61:166-169, May, 1949.

A five-year-old girl with multiple umbilicated vesicular lesions over the face developed a typical dendritic ulcer of the cornea four days after admission. Kaposi's varicelliform eruption and dendritic keratitis are discussed as different phases of sensitization to the virus of herpes simplex. H. C. Weinberg.

GLAUCOMA AND OCULAR TENSION

Christensen, L., and Swan, K. C. **Adrenergic blocking agents in the treatment of glaucoma.** Tr. Am. Acad. Ophth. pp. 489-498, May-June, 1949.

Two new drugs of the adrenergic blocking group are analyzed and their results reported in 18 consecutive cases of acute glaucoma which did not respond to other treatment. These drugs are Dibenamine N-N-dibenzyl-B-chlorethylamine hydrochloride), and SKF #194 (N-B-chlorethyl - N - benzyl - B - phenyl - isopropylamine hydrochloride). Dibenamine, a tissue irritant, is injected intravenously in doses of 4 to 5 mg. per kilogram of body weight. Because of its possible effect on the cardiovascular system, especially in hypertensive patients, bed rest for 36 hours is desirable after its use. Dibenamine causes miosis by relaxing the iris dilator. The immediate decrease of ocular tension ranged from 11 to 40 mm. This action is not altered by mydriatic or cycloplegic drugs. In several patients, repeated doses of Dibenamine were administered at intervals of several days. The hypotensive action of the drug decreased with subsequent use. It is not yet known whether supplementary local treatment influences the hypotensive effect of Dibenamine. SKF #194, is closely related to Dibenamine physiologically. In animals' eyes it is more effective than Dibenamine, but it has not yet been used in human eyes.

Chas. A. Bahn.

Esente, I. The Bloomfield-Lambert test on normal, glaucomatous, and hypertensive individuals. Boll. d'ocul. 28:77-90, Feb., 1949.

In the Bloomfield-Lambert lability test, pressure of 60 to 70 mm. Hg is applied for one minute and simultaneously one hand is immersed in ice-cold water. If the intraocular pressure exceeds 30 mm. Hg or if there is an increase of more than 9 mm. in the original tension, the test is positive for glaucoma. To evaluate the test clinically and to elucidate its mechanism the authors examined normal and glaucomatous patients without and with previous administration of cortico-

diencephalic depressor drugs, and persons with generalized arterial hypertension. In 20 normal persons, the test provoked increases in tension no greater than 7 mm. Hg accompanied by increase of the retinal arterial diastolic pressure to values which sometimes exceeded the normal by 20 mm. Hg. Administration of barbiturates did not markedly influence the results although a slight decrease of tension and intravascular retinal pressure was often observed. In 13 patients with glaucoma, barbiturates had little influence on the tension. In three patients with acute glaucoma, the test provoked an increase of intraocular pressure of 2 to 4 mm.; the diastolic arterial pressure in the retina of two of these patients increased slightly and decreased in one. This in spite of a 20 mm. increase of the brachial arterial pressure. In one patient with chronic simple glaucoma, the test was followed by a 5 mm. decrease of tension while the pressure in the brachial artery remained unchanged. In three eyes successfully operated on for acute glaucoma and with tension below 30 mm. Hg the test provoked tension increases of less than 9 mm. Hg and increase of the retinal arterial pressure of 6 to 12 mm. Hg. In the normal eyes of two patients with unilateral juvenile glaucoma and with tension below 25 mm. Hg, the test raised the tension by 10 mm.

Twenty-two persons suffering from general arterial hypertension were tested. In 12 of these patients, a decrease of the brachial artery pressure and an increase of both the tension and the arterial diastolic pressure was found; usually the test provoked an increase of all values. In a group of patients with exophthalmic goiter there was dissociation of the values measured. The Bloomfield-Lambert test increased the tension and reduced the intraocular arterial pressure.

Esente believes that both interpretations of the Bloomfield-Lambert test are

justified, that of Bloomfield and Lambert who consider it a measure of a local reaction to general pressure changes, and that of Magitot for whom it is a typical example of thalamic irritation. The clinical value of the test is not diminished by its complicated and not fully understood mechanism.   K. W. Ascher.

François, J. **The aqueous veins after iridencleisis.** Ann. d'ocul. 182:169-176, March, 1949.

The aqueous veins of Ascher which go to form the laminary veins of Goldman definitely contain aqueous and act as valves, especially if the ocular tension is increased. Iris inclusion operations on 61 eyes are reported. Aqueous veins were present in 52 percent as compared with 96 percent of normal eyes. Forty-three eyes with iris incarceration were studied. Aqueous veins were observed in 12 of 19 eyes with filtering cicatrix and in 6 of 24 eyes with closed angles. Of 18 eyes with flat cicatrix, 9 had open angles and of these 8 had aqueous veins and of the 9 with closed angles 5 had aqueous veins.
                        Chas. A. Bahn.

Inciardi, J. A. **Aids in the diagnosis of glaucoma.** New York St. J. Med. 49:836-838, April 1, 1949.

Inciardi says that it rests largely upon the general practitioner whether we shall have a small or a large number of persons blind from glaucoma. A large percentage of patients are likely to be seen first by him. There are approximately 200,000 blind persons in the country of which 20,000 are blind from glaucoma. Inciardi describes the symptoms of glaucoma and points out that unbearable pain after occlusion of the central vein means glaucoma and that secondary glaucoma has probably intervened if an eye with cataract suddenly becomes painful. The possibility of increased intraocular pressure is to be con-

sidered if an ocular injury is followed by congestion, pain, blurred vision, or steamy cornea, or if an eye with uveitis develops increased redness, pain, visual disability and steamy cornea.
                    Theodore M. Shapira.

Posner, A., and Schlossman, A. **Role of inheritance in glaucoma.** Arch. Ophth. 41:125-150, Feb., 1949.

Although the importance of heredity in the pathogenesis of glaucoma is often stressed, only about 90 pedigrees of families with glaucoma have been reported. The authors found that of 373 unselected cases of glaucoma in private practice, 51, or 13.7 percent, showed familial tendencies. In most families the disease follows a similar course in the various affected members. The pedigrees of 27 families are given; all but one showed dominant heredity. The genetic approach may be an aid in the early recognition of glaucoma and in the study of the preclinical and mild phases of the disease.
                        John C. Long.

Ullman, E. V., and Mossman, F. D. **Glaucoma and orally administered belladonna.** Northwest Med. 48:245-246, April, 1949.

Six cases of glaucoma clearly induced or aggravated by the internal use of a belladonna drug are reported. Five of the six eyes had narrow filtration angles. Of all prescriptions filled in local pharmacies 10 percent of those not by ophthalmologists contained belladonna in some form. The seriousness of this often-overlooked factor in glaucoma is emphasized.
                        Orwyn H. Ellis.

Verrey, F. **The behavior of the ocular tension after puncture of the anterior chamber.** Ophthalmologica 117:246-248, April-May, 1949.

At the University Eye Clinic of Zurich

the staff has been interested in the use of the anterior chamber puncture as a diagnostic procedure for a number of years. In a thesis by Strassman these studies will be reported in detail. About 2,500 punctures have been performed on patients. With very few exceptions the effects on the ocular tension are brief. In inflammatory disease the author has never observed an appreciable hypertensive reaction; on the contrary, most of the cases of chronic uveitis of long standing respond with hypotension for twenty-four hours. In hypertensive non-inflammatory disease with increased tension the hypertensive reaction after puncture varies a great deal. The authors could not confirm Kronfeld's view of the value of the anterior chamber puncture as a diagnostic test for certain glaucomas. In one of their patients acute glaucoma was precipitated, but the eye responded promptly to eserine In two cases of noninflammatory glaucoma the tension was normalized for several days by the puncture. In the hypertensive inflammatory ocular conditions the immediate reaction to the puncture varies much more than in any of the other groups. In one case of cyclitis with heterochromia the puncture precipitated an acute attack which was terminated by an iridectomy. In about ten cases of this inflammatory hypertensive type the ocular tension was normalized by puncture for several days to several months. The authors believe that paracentesis is not a method of treatment for simple glaucoma or for secondary hypertension except in a few unusual cases but it can render the service of a preoperative or postoperative temporary decompression operation. Complications are rare (2 in 2,500 cases). Puncture is definitely contraindicated in hemorrhagic absolute glaucoma. Slight and brief fluctuations of ocular tension may be observed in the other eye.   Peter C. Kronfeld.

Verrey, F. **The transconjunctival cyclodiathermy after Weekers.** Ophthalmologica 117:281, April-May, 1949.

The University Eye Clinic of Zürich, where Vogt in 1935 first advocated cyclodiathermic punctures, has apparently given up this operation during the last few years and has adopted the transconjunctival nonperforating technique of Weekers. A flat electrode, 0.8 mm. in diameter, is applied to the sclera through the conjunctiva, 7 mm. from the limbus. Over the entire circumference of the globe 18 to 20 coagulations are made in one sitting. A pyrometric eletrode is used which permits accurate measurement of the amount of heat applied. The current is turned on and gradually increased so as to reach a temperature of 90° C. in 3 to 5 seconds. This temperature is maintained for from 10 to 15 seconds. At the end of the operation the ocular tension is always markedly increased. This rise of tension can be alleviated either by a puncture of the anterior chamber or irrigation of the surface of the eye, between the coagulations, with a cool (35°C.) saline solution. The author has used this operation in 30 eyes of which 4 had infantile glaucoma, 2 juvenile, 8 acute or hemorrhagic, and 11 secondary glaucoma. The number of permanently successful operations is not stated.   Peter C. Kronfeld.

Weekers, L., and Weekers, R. **Non-perforating cyclodiathermy.** Ann. d'ocul. 182: 188-198, March, 1949.

The author considers iridencleisis the operation of choice in almost all primary glaucoma. With it tension was normalized in 96 percent of eyes with chronic glaucoma, in 93 percent with subacute, and in 85 percent with acute glaucoma. If tension persists after iridencleisis, nonperforating cyclodiathermy is considered preferable to cyclodialysis and other operations, because it is more effective,

simpler and less painful. Ten cases of such secondary cyclodiathermy are described.   Chas. A. Bahn.

Weekers, L. and Weekers, R. **The physiopathological foundation and the technique of the iris inclusion operation.** Ophthalmologica 117:305-324, June, 1949.

"Iridencleisis appears to be destined to occupy the first place among the anti-glaucomatous operations." On the basis of their own observations the authors do not consider the iridencleisis to be a filtering operation. A filtering scar, if it should develop after iridencleisis, is of only secondary importance. The paper consists of three parts: 1. the mechanism of the normalization of tension after iridencleisis, 2. the importance of the postoperative scar on the surface of the globe, and 3. the effect of the operation upon the function of the aqueous veins. In the hands of the authors the iris inclusion operation is successful in 96 percent of the chronic glaucomas, in 93 percent of the subacute, in 85 percent of the acute glaucomas, and in 70 percent of secondary. The criterion of success is an ocular tension below 25 mm. Hg (Schiøtz, 1924). Especially in the subacute and in the acute glaucomas the iridencleisis, if successful, causes the ocular tension to return to normal, that is, to the range between 17 and 24 mm. In the chronic glaucomas the postoperative tension varies within somewhat wider limits. If the distribution of postoperative tensions in glaucomatous eyes is compared with the distribution of ocular tension in normal eyes, almost identical curves are obtained. The diurnal variations of ocular tension were studied in two cases of bilateral chronic glaucoma several months after successful iridencleisis on one eye. The operated eyes still described typical diurnal variations though on a very much lower level than the unoperated eye. The

Seidel test has been almost invariably negative. No relationship could be found between the size of the scar and the ocular tension. In the cases with markedly bullous or cystic scars the tension was definitely lower. In these cases the authors admit the possibility of fistulization as a possible auxiliary but not indispensable factor. Averse to the theory of fistulization, the authors consider two other possibilities whereby a bullous scar could account for a lower ocular tension. The proximity of the bullous scar might modify the elasticity of the cornea and thereby introduce a "false" reading. The cystic cavity of the bleb with its watertight partitions might also represent a decompression chamber of greater or lesser elasticity and thereby influence the ocular tension. The important fact that very often the operative scars are flat in the presence of normal ocular tensions seems to exclude filtration altogether. The principal mode of action of iridencleisis is a different one.

Marked lowering of the ocular tension by the iridencleisis reduces the number of visible aqueous veins which are direct outlets of the trabecula and canal of Schlemm. The authors consider the latter as just an auxiliary system to the venous system of the anterior uvea which plays the preponderant role in the resorption of the aqueous. After a successful iridencleisis, this auxiliary system is not needed and it is for that reason that some of the aqueous veins disappear.

The technique of iridencleisis as practiced by the authors is described.
                    Peter C. Kronfeld.

Weinstein, Paul. **The treatment of glaucoma with furmethide and di-isopropylfluorophosphate.** Ophthalmologica 118:76-79, July, 1949.

During his recent trip to the United States, Weinstein observed the results

obtained with furmethide and DFP. On a group of glaucoma patients, in Budapest, he made and now reports observations similar to those reported by Uhler (Amer. J. of Ophth. 26:17, 1942) and by Leopold (Arch. of Ophth. 35:1, 1946).

Peter C. Kronfeld.

CRYSTALLINE LENS

Denig, Rudolph. **Early and late sequelae of the discision of congenital nuclear cataract and its variations.** Klin. Monatsbl. f. Augenh. 114:197-202, 1949.

The author discusses the dangers of discision in the treatment of congenital nuclear cataract and points to the damaging effect of lenticular remnants on the uveal tract. The frequent occurrence of late detachment of the retina after such discision is another result of the damage to the uveal tract and retina by lens protein. One of the author's patients developed a trophoneurotic damage of the corneal epithelium. Denig advocates optic iridectomy in suitable cases, or loop extraction. He prefers the slight loss of vitreous to the complications following a discision. (References.)

Max Hirschfelder.

Fanta, H. **Cataract formation after Elliot's trephining and Holth's iridencleisis.** Arch. f. Ophth. 148:643-657, 1948.

The formation of cataract, which was more frequent after Elliot's operation, can be more probably ascribed to postoperative iritis, rather than to postoperative hypotony.   Ernst Schmerl.

Harrington, D. O. **The mechanics of intracapsular cataract extraction.** Tr. Am. Ophth. Soc. 46:294-317, 1948.

The fundamental physical principles underlying the dislocation and intracapsular delivery of the lens is discussed. It can be demonstrated by slit lamp microscopy, by gonioscopic observation, dur-

ing actual intracapsular cataract extraction on the living eye, on animal eyes and on human cadaver eyes, that the rupture of the zonular lamella of the lens is accomplished primarily by the production by *external pressure of a wedge of vitreous* tissue which is made to insert itself between the equator of the lens and the ciliary processes. The deformity of the vitreous can be produced at whatever site is desired. The normal vitreous is a tissue and cannot be considered as a fluid in which pressure at one point is transmitted equally to all other parts. Certain safety factors in intracapsular cataract extraction may be reevaluated in the light of these basic principles.

David Harrington.

Jorio, A. **Two cases of cataract associated with skin diseases.** Rassegna ital. d'ottal. 18:17-33, Jan.-Feb., 1949.

The author discusses the various characteristics of syndermatic cataracts and reviews the literature on this rare condition. The first patient demonstrated the effects of the Rotmund-Werner syndrome, and in the second the syndrome of Sjögren was added to this. The latter association is the first reported in the literature. From the clinical examination and laboratory findings the writer considers the cause to be an endocrine dysfunction of the genital glands and other glands of the endocrine system may participate. (6 figures.) Eugene M. Blake.

Jaeger, A. **Collapse of the sclera after cataract surgery.** Klin. Monatsbl. f. Augenh. 114:148-151, 1949.

The sclera may sink in after lens extraction because of loss of an unusual amount of anterior aqueous with a deeply situated subluxated lens, or posterior aqueous with seclusion of the pupil or loss of vitreous. The condition corrects itself, if the loss is not too great. The

problem of proper closure of the wound is discussed. It is not difficult, if the collapse involves the region of the insertion of the muscles. In the region of the ciliary body it prevents the coaptation of the edges of the section. If one avoids too much tension in suturing the conjunctival flap, the incongruence will correct itself in a few days. Max Hirschfelder.

Knüsel, O. **Electric cataract.** Ophthalmologica 117:299, April-May, 1949.

The case of a thirteen-year-old boy who developed a cataract in his left eye one year and in his right eye six years after electric shock illustrates the greatly variable latent period of electric cataract. Peter C. Kronfeld.

Papolczy, F. **Statistical data of my cataract operations performed with a new suture of the sclera.** Brit. J. Ophth. 33:296-305, May, 1949.

A new suture is presented which has been used with good success in 325 cases. A 6-0 black nylon suture is placed through the conjunctiva and sclera parallel to the limbus and 1 mm. above it at 12 o'clock. Section is made with a knife and brought to the suture. A conjunctival flap is made with scissors and brought down over the cornea. A round pupil and intracapsular delivery are then accomplished and the wound closed with the single preplaced suture. Morris Kaplan.

Perera, Chas. A. **A simple appositional suture in operations for cataract.** Tr. Am. Ophth. Soc. 46:184-191, 1948.

A suture is described which is placed after keratome incision and before scissors enlargement of the wound. The exact approximation of the wound edges results in accurate closure, rapid reformation of the anterior chamber and only one iris prolapse in 100 cases. David Harrington.

Sedan, J., Levrat, M., and Paufique, L. **Petechiae test in diabetic cataract.** Ann. d'ocul. 182:177-187, March, 1949.

The test is made by applying a sphygmomanometer cuff to the upper arm which is inflated to the maximum arterial tension less 2 cm. and left for five minutes. If the test is positive, petechiae appear, and are recorded as +1 to +4 on the basis of their size and number. A positive test indicates a probable retinal vascular degeneration and probable unfavorable visual prognosis for cataract extraction. The petechiae on the arm are considered an index to probable hemorrhages in the retina. Twenty-nine cases are briefly discussed to illustrate the value of this test which the authors believe should be more widely used to determine the risks of cataract extraction in diabetics. Chas. A. Bahn.

11
RETINA AND VITREOUS

Blanchi, G. **Angioneurotic degeneration of the macula.** Rassegna ital. d'ottal. 18:34-43, Jan.-Feb., 1949.

The retinal alterations consisted of constriction of retinal vessels and of fine, and originally, limited pigmentation of the macular region. Early, active treatment with vasodilators and vitamin B resulted in but moderate improvement. Further studies of the circulatory system will probably confirm the opinion that there is an angioneurotic factor as in the three cases reported. Study of the endocrine functions, particularly of the hypophysis and the diencephalic centers, may prove the importance of this region in the regulation of the cerebral and retinal circulation. Eugene M. Blake.

Bruna, F. **Ocular complications in Werlhof's disease (essential thrombopenia).** Boll d'ocul. 28:41-56, Jan., 1949.

Few cases of eye involvement in Werl-

hof's disease have been described. Bruna observed a 16-year-old girl with lesions similar to retinitis proliferans in the region of the optic disc and with pigment rarefication in the macula of both eyes. Werlhof's disease was the probable cause. (References.)   K. W. Ascher.

Candian, B. **The fundus oculi of the newborn.** Rassegna ital. d'ottal. 18:3-16, Jan.-Feb., 1949.

The eyegrounds of 35 babies were examined in mydriasis within a few hours to three days after birth. Twenty-six showed pallor of the disc, in six it was of reddish hue and in three intermediate in color. Retinal hemorrhages were observed seven times, papilledema six times, and in only two was the refraction emmetropic. Hypermetropia of two to eight diopters was measured with the ophthalmoscope.

A table gives many details of each case examined and three excellent colored plates depict the peripheral palor of the fundus and of the disc and the various types of retinal hemorrhage. A good bibliography accompanies the article. (4 figures, references.) Eugene M. Blake.

Carreras Matas, B. **A conception of tapetoretinal degeneration.** Arch. Soc. oftal. hispano-am. 9:265-279, March, 1949.

A review of the literature and several personal observations led the author to believe that the mutation which deprives the cells of the sensory retinal epithelium and the pigment epithelium of essential elements, is the cause of tapetoretinal degenerations. The clinical implication of this theory leads to therapeutic attempts with drugs which stimulate the circulation of the choriocapillaris and provide abundant nutrition for the external layers of the retina, and with those which regulate the neurovegetative system and normalize the function of the glands of internal secretion. The intense vitamin

therapy and tissue therapy after Filatov may be tried. The retina should be protected from bright light, which may be within safe limits for normal eyes but is excessive for degenerate eyes.
        Ray K. Daily.

Costi, C. **Posterior detachment of the vitreous and rupture of the hyaloid.** Arch. Soc. oftal. hispano-am. 9:390-396, April, 1949.

In two patients, 44 and 24 years old, both emmetropic, and with history of trauma, anterior vitreous opacities indicated the presence of uveitis. The ophthalmoscopic appearance of the detachment and perforations in the hyaliod membrane are described in detail. The pathogenesis is discussed, and the author believes that a primary uveitis leads to a thickening of the hyaloid membrane, which, losing its elasticity, is easily torn, through slight trauma or effort. The degenerated and liquefied vitreous insinuates itself through the hole, in the same manner that it does in retinal ruptures. It is believed that improved exploration of the hyaloid membrane will reveal that ruptures in it are not as rare as is supposed. (3 figures.)   Ray K. Daily.

Czukrasz, Ida. **A Case of branch embolism of the central retinal artery.** Ophthalmologica 118:66-68, July, 1949.

A nurse, 26 years of age, presented herself in the eye clinic one hour after a spontaneous blackout of her left eye. The right eye was found to be normal, the left eye presented the picture of an embolism of the inferior papillary artery. The vision was reduced to light perception. Thorough examination revealed no other circulatory or cardiac abnormality. The patient was treated chiefly with a vasodilator of the acetylcholine group called stabilocholin which was used retrobulbarly and subcutaneously. She was also given several inhalations of amyl nitrite

and a paracentesis was done a few hours after the blackout. The vision improved gradually. Five days after the onset the patient was discharged from the clinic with a visual acuity of 5/8 and a moderate constriction of the upper half of the field.

Peter C. Kronfeld.

Delaney, A. J., and Rhoades, A. L. **Angioid streaks of the retina, report of a case.** U. S. Naval Med. Bull. 49:296-299, March-April, 1949.

A case of angioid streaks of the retina is presented, because of its rarity and its varied and apparently unrelated associated clinical findings. At the time the paper was written no evidence of pseudo-xanthoma elasticum appeared in the patient. Lesions in the mouth similar to pseudoxanthoma elasticum proved to be Fox-Fordyce disease. There was no X-ray evidence of bony change suggestive of Paget's disease, sometimes an associated finding.   Theodore M. Shapira.

Duke-Elder, Stewart. **The relation between peripheral retinal cysts and dialyses.** Brit. J. Ophth. 33:388-389, June, 1949.

The author reports a case of a retinal cyst in the extreme periphery. Six months later it had doubled in size and extensive dialysis of the retina was now present. Diathermy was performed with successful reattachment.   Orwyn H. Ellis.

Esente, Ivan. **The clinical and pathogenetic aspects of Purtschers's and Berlin's retinitis (commotio retinae).** Arch. di ottal. 52:195-217, July-Aug., 1948.

The author discusses these two forms of traumatic retinal disturbances. The former, retinal contusion following indirect trauma to the bulb, was described by Purtscher in 1910 and called "angiopathia retinae traumatica." The latter, called "commotio retinae" arises from di-

rect injury to the eyeball and was described by Berlin in 1874. Experiments carried out on rabbits and dogs under general anesthesia, showed an absence of the ocular signs typical of Purtscher's retinitis. These results are not sufficient to modify the author's theory that Purtscher's disease is an angioneurotic retinitis from indirect trauma.

Francis M. Crage.

Fajardo, R. M. **Congenital macular displasia associated with ocular anomalies.** An. Soc. mex. de oftal. 22:310-315, 1948.

The lesion was associated with persistence of the hyaloid artery and prepapillary membrane; the possibility of choroiditis about the seventh or eighth month of intrauterine life is suggested. (2 figures, references.)   W. H. Crisp.

Franceschetti, A., and Balavoine, C. **The prevention of retinal detachment by surgical therapy.** Ophthalmologica 117:259-263, April-May, 1949.

A question of when and how to subject retinal tears without detachment to surgical therapy has been discussed repeatedly at the meetings of the Swiss Ophthalmological Society. Weber recommended such surgical treatment in the presence of the following "unfavorable factors": detachment in the other eye, location of the tears in the upper quadrants, progressive degeneration of the retina, myopia, and hereditary tendencies. To these the authors add two other factors, namely the patient's age, and poor visibility of the fundus sector in which a detachment is most likely to occur. The authors have found bilateral progressive retinal degeneration more common in young people and they have been impressed by the occurrence of retinal detachment in those fundus sectors where the visibility was poorest because of dislocation of the lens in Marfan's syndrome.

Peter C. Kronfeld.

François, Jules. **Contribution to the study of tapeto-retinal degeneration.** Ophthalmologica 118:1-29, July, 1949.

The author reports a French family six members of which showed a bilateral degenerative disease of the central portion of the retina and choroid. In the early stages of the disease it resembled closely Stargardt's heredomacular degeneration. In the later stages a very marked choroidal sclerosis was added to the picture. The hereditary transmission followed the dominant mode. The author prefers the term tapeto-retinal degeneration for this disease to indicate that, just as in true pigmentary degeneration of the retina, the tapetum or its equivalent is involved in the very early stages of the disease.

To demonstrate the close relationship between true pigmentary degeneration of the retina and hereditary macular degeneration, the author reports another family in which one sister had a typical retinitis pigmentosa and one brother a macular disease of the Stargardt type.

Peter C. Kronfeld.

Hager, Hugo. **Thrombo-angiitis obliterans and the eye.** Klin. Monatsbl. f. Augenh. 114:238-247, 1949.

A patient with tobacco amblyopia presented a clinical picture of thrombo-angiitis obliterans of the extremities. The fundus showed temporal pallor of the disc, narrow arteries, tortuous veins and slight degeneration of the macula. It is suggested that in tobacco amblyopia the degenerative changes in the nerve and the retina are possibly not caused by toxin, but by thrombo-angiitis obliterans. In a second case of thrombo-angiitis obliterans the patient used tobacco excessively, had small aneurysms and partial obliteration of the vessels in part of the fundus. The vision was only slightly reduced. The author compares these findings with those usual in periphlebitis retinae and concludes that the latter has, contrary to the opinion of Marchesani, nothing to do with thrombo-angiitis obliterans. (4 figures, references.) Max Hirschfelder.

Huber, A. **Cerebral and retinal angiopathy.** Ophthalmologica 117:265, April-May, 1949.

In hypertensive cardiovascular disease of the benign as well as of the malignant type the parallelism between cerebral and retinal vascular changes is not very close. The likelihood of a cerebral vascular accident cannot be determined from the retinal findings. The parallelism between the renal and retinal vascular changes however is always very close. The author quotes in detail two cases of Buerger's disease with thrombo-angiitic obstructions of large cerebral arteries and pathognomonic eye findings. In both cases ophthalmoscopy suggested arterial occlusion as the main basis of the systemic disease. On the other hand, numerous cases are recorded in the literature in which, in the presence of advanced Buerger's disease, the eye grounds were practically normal. Peter C. Kronfeld.

Klien, B. A. **Histopathologic aspects of retrolental fibroplasia.** Arch. Ophth. 41: 553-561, May, 1949.

The author believes that retrolental fibroplasia is in some way connected with angioblastic overgrowth of the primary vitreous which may occur at any stage of gestation after formation of the primary vitreous has started. It is the stage in which the retina becomes involved that determines different and characteristic histologic pictures of retrolental fibroplasia. Ralph W. Danielson.

Moginier, A. **The treatment of retinitis pigmentosa with placental tissue and nicotinic acid.** Ophthalmologica 117:287-290, April-May, 1949.

Thirteen patients with retinitis pig-

mentosa received one or two subconjunctival inoculations of placental tissue and were followed for eight months. In eight the visual acuity and the visual field showed improvement. The dark adaptation remained unimproved. Four other patients were given daily intravenous injections and oral doses of 100 mg. of nicotinic acid for two weeks. The acuity improved in all of them. The visual field was only slightly influenced. Although one can not cure the advanced cases of retinitis pigmentosa, one may hope to keep early patients on a visual level which will permit them to lead a normal life.   Peter C. Kronfeld.

Neuenschwander, M. **Our experiences with placenta therapy of retinitis pigmentosa.** Ophthalmologica 117:290-292, April-May, 1949.

Fifty-seven patients with retinitis pigmentosa received placenta therapy after Filatov, in the form of either subconjunctival injections of placental blood serum or of subconjunctival implantation of placental tissue. The author reports "his six best cases" and draws the following conclusions. "Placenta therapy is not an infallible means of treatment, (but) there are cases (of retinitis pigmentosa) which are definitely improved by placenta therapy. . . . This improvement may last a whole year. . . . Although only a small percentage of cases can be improved, we believe that placenta therapy should be tried in every case of retinitis pigmentosa."   Peter C. Kronfeld.

Oxilia, E. **Tissue therapy in retinitis pigmentosa. Late results.** Ann. di ottal. e clin. ocul. 74:499-511, Sept., 1948.

From personal experience with 30 patients and from a review of the literature Oxilia concludes that if preserved and autoclaved tissue is used in exact accordance with Filatov's method the successes obtained are indisputable. The action does not depend on a colloidoclastic shock. The successes depend on the state of preservation of the vision, but are independent of the age of the patient. Best results are obtained early in the course of the disease, but even late, when destruction is great, some improvement may occur. Most successful are subconjunctival implantations of placenta, especially if accompanied by intramuscular injections of placental extract. Injections of cod liver oil are equally effective but are badly tolerated. Vision, visual fields, and light sense may all show improvement. No changes are observed in the ophthalmoscopic picture, but in some cases Oxilia noted a drop in the retinal arterial pressure. Rapidity and duration of therapeutic effects vary with the method employed and with the state of the visual functions. (References.)
          Harry K. Messenger.

Poos, F. **Ascending atrophy of the intraocular vascular system, retinal isobars and progressive concentric contraction of the visual field.** Klin. Monatbl. f. Augenh. 114:151-161, 1949.

The author attempts to correlate the factors which determine the characteristic concentric progression of certain defects in the visual field. The pressure within the retinal arteries decreases in all radii from the center of the retina toward the periphery and zones can be delimited by isobars. The center of these circles is not the papilla, but the macula. The embryonic development of the retinal vascular system, of which the arching and more strongly developed temporal arteries supply a larger retinal field, make this fact comprehensible. Concentric contraction of the visual field starts when the lowest peripheral pressure does not suffice to provide the proper blood supply in the capillary system, or when the increased or normal intraocular pressure exceeds the normal or decreased vascular pressure.

Hand in hand with the consequent peripheral retinal atrophy goes a progressive shrinkage of the vascular tree. These considerations explain the progressive and irreparable concentric contraction which is marked by isobars between the living and non-living retinal tissue. A special theory is developed for the pathologic physiology in retinitis pigmentosa. (References.) Max Hirschfelder.

Poos, F. **The origin of infarcts after vascular closure in brain and retina.** Klin. Monatsbl. f. Augenh. 114:247-251, 1949.

There are no true endarteries in the brain and retina and arterial and venous anastomoses do exist. The author explains the origin of the anemic infarct after arterial closure by a compression of the empty capillaries by intracranial or intraocular pressure. The normal balance between intracapillary pressure and the pressure of the surrounding region is disturbed when the capillary pressure sinks to almost zero after arterial infarct. The hemorrhagic infarct after closure of a vein does not lead to a collapse of the capillaries, whose pressure is actually elevated. This explains the lesser degree of functional disturbance after venous closure and the possibility of considerable recovery through collateral circulation. The term "compression infarct" characterizes the anemic infarct, while the term "congestion infarct" describes the hemorrhagic infarct. (References.)
Max Hirschfelder.

Puig Solanes, M. **Anticoagulating treatment of retinal vascular occlusion.** An. Soc. mex. de oftal. 22:237-262, 1948.

Rather weakly conclusive statistics lead the author to conclude that anticoagulant therapy is the fundamental treatment for obstruction of the retinal veins and is auxiliary but necessary in arterial occlusions. The results are felt to be on the average much better in obstruction of branches of the central vein than in that of the main trunk. (Statistical tables, 14 graphs, references.) W. H. Crisp.

Puig Solanes, M. **Retinal angioscopy in hypertensive patient operated upon by Smithwick's procedure.** (sympathectomy). An. Soc. mex. de oftal. 22:99-112, 1948.

In the first weeks after the operation one frequently sees narrowing of the retinal arterioles, with increase in the "edematous" papillo retinal lesions. In a few months an angiospasm and the "edematous" lesions may disappear, but with persistence of arterial contraction. The retinal vascular changes in these operated patients are independent of the effects upon arterial tension and the effects produced upon the general condition of the patient. The author supposes that similar modifications may be produced in other circulatory areas of the organism, especially the brain. (References.) W. H. Crisp.

Redslob, E. **Chorioretinal pigmentary degeneration with paradoxical evolution.** Ann. d'ocul. 182:443-448, June, 1949.

Tapeto-retinal degeneration is briefly described and a case is reported. A 51-year-old woman with defective night vision and a concentrically contracted field since childhood had noticed failing central vision since 1938. Central vision is 8/200 in both eyes. A central scotoma of 20 to 30 degrees is surrounded by a normal zone of 20 to 30 degrees and the periphery is blind. The retina and disc are ophthalmoscopically normal in the central zone. In the intermediate zone, the lesion resembles the constitutional type of pigmentary retinal degeneration with pigment migration into the inner retinal layers. In the periphery there is the salt and pepper fundus usually ascribed to congenital lues. Both congenital syphilis with negative serologic

reactions and a constitutional degenerative process must be considered.

Chas. A. Bahn.

Reese, A. B. **Persistence and hyperplasia of primary vitreous; retrolental fibroplasia—two entities.** Arch. Ophth. 41:527-552, May, 1949.

Reese presents an excellent discussion of this problem and contrasts the two conditions. Both have in common the persistence of the primary vitreous as the basic congenital lesion, but there is an important difference. In persistence and hyperplasia of the vitreous the primary vitreous remains in toto and, when the secondary vitreous forms, occupies its normal position in a funnel-shaped space behind the lens. There is merely a persistence of the primary vitreous and hyperplasia. In retrolental fibroplasia only a portion of the primary vitreous remains in the region of its base but it is adherent to a portion of the inner layer of the optic cup. As the secondary vitreous forms, it tends to compress and isolate the primary vitreous. This occurs everywhere but in the region where adhesion has taken place, and there the retina becomes detached. In addition, there may be hemorrhage from the persistent vascular primary vitreous, leading to organization, contraction and further retinal detachment. Attempts at relief by surgery have been disappointing, but roentgen treatment of the angiomatous tissue early may be of value.

Ralph W. Danielson.

Reese, A. B., and Blodi, F. C. **Retrolenticular fibroplasia.** An. Soc. mex. de oftal. 22:208-216, 1948.

This is an excellent summary in Spanish of the history of the subject, emphasizing the importance of the condition as a cause of blindness in children of preschool age. (References.) W. H. Crisp.

Rychener, R. O. **Retinoblastoma in the adult.** Tr. Am. Ophth. Soc. 46:318-326, 1948.

The clinical and pathologic study of the fifth case of retinoblastoma in an adult is recorded (Illustrations.)

David Harrington.

Schulte, D. **Spontaneous reversal of the arterial flow in the retina.** Klin. Monatsbl. f. Augenh. 114:251-259, 1949.

After embolism of a large branch of the retinal artery the author observed centripetal flow of blood in some peripheral retinal arteries. The phenomenon is explained by the theory that the capillary net has anastomoses with healthy regions of the retina which raise the capillary pressure sufficiently to overcome the vastly decreased pressure in the arteries of the affected part. (3 figures, references.)

Max Hirschfelder.

Shelburne, S. A. **Retinal arteriovenous nicking; a long term study of the development of arteriovenous nicking in hypertensive patients.** Arch. Int. Med. 83:377-381, April, 1949.

The author presents drawings made from actual patients showing various degrees of retinal arteriovenous nicking, early, moderate, and definite.

A study of 15 cases over a long period proved that early arteriovenous nicking progresses to moderate or definite arteriovenous nicking over a period of years and that the categoric classification previously reported actually represents degrees of the same lesion. These cases show in some measure the time required for progression from first degree of the lesion to the others and the many years required for the formation in hypertensive patients of the fully developed lesion which is called definite arteriovenous nicking.

Theodore M. Shapira.

Vila Ortiz, J. M., Maximo Soto, C., Staffieri, J. J., and Rose, Juan. **Diabetes**

and the ocular fundus. Arch. Soc. oftal. hispano-am. 9:245-264, March, 1949.

A review of the literature is followed by a tabulated report of the author's own investigations to determine the pathogenesis of the diabetic changes in the fundus. In 50 diabetic patients with ocular complications the arterial presure, renal function, proteinemia, cholesterinemia, calcemia, vascular fragility, and changes in the hemostatic mechanisms were noted and related to the ocular changes, but no correlation could be determined between the degree of these abnormalities and the gravity of the fundus changes. Only one patient had a hypercholesterolemia and the fundus picture was that of retinal sclerosis. In all who had a normal fundus the renal function was normal.

Ray K. Daily.

Vogelius, Henning. **The increasing frequency of diabetic retinopathy.** Acta ophth. 27:99-111, 1949.

The material which was the basis for this investigation was too small to permit of definite conclusions, and the author uses published data to support his statement that there is an increase in the incidence of retinopathy, which he attributes to inadequate insulin therapy and to the introduction of a free diet for diabetics.

Ray K. Daily.

Weber, E. **Retinal tears without detachment.** Ophthalmologica 117:263-264, April-May, 1949.

The author restates his findings that retinal holes without detachment can be found in two out of every thousand office patients. A typical case is described in detail. Peter C. Kronfeld.

OPTIC NERVE AND CHIASM

Benedict, M. L. **Etiology and treatment of optic neuritis.** Texas St. J. Med. 45: 126-130, March, 1949.

The subject of optic neuritis is covered completely and comprehensively. A cause which is frequently overlooked is plumbism. The other diseases simulating optic neuritis are mentioned. Over 50 percent of retrobulbar neuritis and a large percentage of optic neuritis is due to multiple sclerosis. Foreign protein therapy, particularly intravenous typhoid vaccine is the treatment of choice in acute cases and vasodilators are used in chronic toxic optic neuritis.

Donald T. Hughson.

Di Luca, G. **Optic nerve atrophy from methyl alcohol poisoning.** Boll. d'ocul. 28:17-31, Jan., 1949.

Two patients were observed with atrophy of the optic nerves due to methyl alcohol and one to quinine poisoning. The differential diagnosis and pathogenesis are discussed. Ten visual field diagrams and a differential diagnostic table make the data perspicuous. (References.) K. W. Ascher.

François, P. **Hyaline verrucosities of the papilla.** Ann. d'ocul. 182:249-278, April, 1949.

Hyaline is a polymorphous compound, more dense than colloid but chemically similar, which is deposited in the tissues as the result of local metabolic abnormalities. There are 198 reports of hyaline verrucosity in the papilla in the literature. The lesion may occur as a congenital anomaly; or as a postnatal, slowly-progressive process which may follow mechanical pressure or chemical irritation. Central and peripheral vision may be reduced. One to five or more verrucosities may be located in the papilla or in the optic nerve behind the eyeball. Several forms are mentioned. They occur in the phakomatoses and in Bournaville's disease, in ocular diseases such as retinal pigmentary degeneration, primary and secondary glaucoma, malignant uveal tumors, degenerative uveitis, retinal de-

tachment, and in brain tumors and some vascular diseases. They are essentially a degenerative processs involving primarily neuroglia. One of the six cases reported was secondary to a cerebral abscess which produced a lateral hemianopsia. All of the cases reported had field defects. Campimetric examinations should be made with a 1/1000 target on a Bjerrum Screen. (92 references.)   Chas. A. Bahn.

Klauder, J. V. **Penicillin treatment of syphilitic primary optic atrophy.** Am. J. Syph., Gonor. and Ven. Dis. 33:234-242, May, 1949.

This is an interim report on the treatment of 56 patients with syphilitic primary optic atrophy, begun in April, 1944. The syphilis was acquired in 53 and congenital in three. The results were variable but 32 patients showed no increase in the optic atrophy. No correlation could be made between the spinal fluid response during penicillin treatment and the progress of the optic atrophy. Patients who have had treatment before the penicillin therapy seem to retain the little vision they have. (3 tables.)

H. C. Weinberg.

Tornquist, Ragnar. **Hyaline bodies (Drusen) as the cause of atrophy of the optic disc.** Acta ophth. 27:1-9,1949.

Three patients developed reduced visual acuity and contraction of the visual fields during a few months. The visual defects were not complete, but numerous islands of perception within the defective field were preserved. In all three cases the discs were slightly pale, and top shaped in form and contained hyaline bodies. (6 visual fields.)   Ray K. Daily.

NEURO-OPHTHALMOLOGY

Agundis, Teoledo, Jr. **Romberg's facial trophoneurosis.** An. Soc. mex. de oftal. 22:153-166, 1948.

Two cases of this extremely rare disease, a progressive facial hemiatrophy, first described by Romberg in 1846, are reported. It occurs between the ages of 18 and 30 years, without previous abnormality and is initiated by such sensory disturbances as pain, tenderness and hyperesthesia in areas innervated by one or more branches of the trigeminal nerve. In the affected half of the face gradual atrophy of skin, muscles, and bony framework develops. The orbit and accessory nasal sinuses may be involved. The cause is unknown and no treatment is effective. (6 figures, references.)   W. H. Crisp.

Camisacca, Lionello. **The opticokinetic post-nystagmus in cranial traumas.** Riv. oto-neuro-oftal. 23:284-297, July-Aug., 1948.

In 19 patients who had sustained a trauma of the head, and in 19 normal persons as control, the test for opticokinetic nystagmus was positive in a few cases and in these cases the oscillations were isolated and not well marked. The writer's findings were not in accord with those obtained by Merloo of Holland who found oscillations that lasted up to one half minute. (References.)

Melchiore Lombardo.

Grasso Canizzo, E. **Unusual case of partial third nerve paralysis during a staphylococcic septicemia.** Boll. d'ocul. 28:110-116, Feb., 1949.

This rare condition was due to staphylococcus albus infection and was cured in a few weeks by administration of penicillin and of sulfathiazol. (References.)

K. W. Ascher.

Lauber, H. **Scintillating scotoma.** Klin. Monatsbl. f. Augenh. 114:168-171, 1949.

Lauber describes scintillating scotomas which he himself experienced during the past six years, at first only twice annually, but lately every 6 to 10 weeks. One attack

was followed by a loss of consciousness and another attack was combined with alexia. The author ascribes the phenomena to ophthalmic migraine caused by vascular spasms in the field of the vertebral and basilar arteries. (References.)

Max Hirschfelder.

Rubino, A., and Esente, I. **The eye and the diencephalon. (VII) The glycemic curve from addition of glucose and "photoglycemic" reflex in patients affected by pigmentary degeneration of the retina.** Riv. oto-neuro-oftal. 23:244-249, July-Aug., 1948.

In eight patients a glycemic curve was obtained which could be referred to the diencephalic glyco-regulator centers. The photoglycemic reflex was normal.

Melchiore Lombardo.

Tornquist, Ragnar. **An anomaly of the retinal vessels (so called aneurysma cirsoides) sometimes combined with symptoms from the central nervous system.** Acta ophth. 27:11-17, 1949.

Tornquist reports a case of a racemose aneurysm, in the left fundus of a 31-year-old woman, who had persistent headache and a slight right-sided hemiparesis which were tentatively ascribed to meningitis. The left eyeground presented a picture of typical racemose aneurysm, with a number of aneurysmal dilatations of the arteries near the disc, and there were a few retinal pigment spots. There were no visual disturbances and other examinations were essentially negative. The literature is reviewed. (1 figure.)

Ray K. Daily.

Wilson, W. C. **Inequality of the pupils in head injury; a clinicopathologic study.** Arch. Neurol. and Psychiat. 61:385-401, April, 1949.

In a series of 451 cases of anisocoria there were 192 clinical cases and 259 clinicopathologic. The number of cases of anisocoria with normally reacting pupils was inversely proportional to the severity of the lesions. In the majority of the cases the condition was associated with hematomas from 0.3 to 1.5 cm. in thickness. The hematoma was homolateral with the dilated pupil in the majority of the cases. By observations of the functional state of the unequal pupils it is possible to estimate the severity, thickness and laterality of the lesion.

In 166 cases (36 percent of the total number) there was an altered reaction to light with impingement on the oculomotor nerve. In the remaining 285 cases (64 percent) there was a brisk, reaction to light and no dysfunction of the extraocular muscles; autopsy, when performed, showed no evidence of impingement on the oculomotor nerve. The majority of the cresyl violet preparations of the premotor cortex showed no change, or only increased perineural and perivascular spaces with pale-staining cellular elements, therefore correlation was not great between the clinical evidence indicating interrupted physiologic continuity and the degree of demonstrable pathologic change.

EYEBALL, ORBIT, SINUSES

Chavira, R. A. **Clinical notes concerning fractures of the orbit.** An. Soc. mex. de oftal. 22:175-190, 1948.

Fourteen clinical cases are summarized with details of ophthalmologic and neurologic symptoms. (Reference.)

W. H. Crisp.

Giggleberger, H. **Cholesteatoma of the orbit.** Klin. Monatsbl. f. Augenh. 114:206-211, 1949.

Two cases of exophthalmus are described. X ray revealed hyperostosis of the bony wall of the orbit as well as rarefaction of bone. The cause was cho-

lesteatoma, one confined to the orbit, the other one broken through into the cranial cavity. Dermoids may give the same clinical appearance. Early surgical removal is advised to avoid a breakthrough of the tumor into the frontal sinus and the cranial cavity. (3 X-ray figures, references.)   Max Hirschfelder.

Goodyear, H. M. **Ophthalmic conditions referable to diseases of the paranasal sinuses.** Arch. Otolaryng. 48:202-208, Aug., 1948.

Goodyear presents his observations in cases of retrobulbar neuritis in patients with normal ethmoid and sphenoid sinuses. In these cases vision frequently returns to normal after the opening of the sphenoid sinus and posterior ethmoid cells on the side of the optic lesion.

In the past 15 years, he has observed that the injection of 27-percent iodized oil into the sphenoid will produce the same spectacular result as is obtained by surgical intervention. In acute swelling and edema about the eye after an acute infection of the frontal sinus, chemotherapy and external drainage is advised. Recurring corneal ulcers demand a careful survey of the paranasal antrums. Acute suppurative ethmoiditis in an infant is frequently mistaken for dacryocystitis. Patients with tumors in the paranasal sinuses often go to the ophthalmologist first because of disturbed vision and pain of the eye and frequent double vision.
                              Theodore M. Shapira.

Pfeiffer, R. L., and Nicholl, R. J. **Dermoids and epidermoids of the orbit.** Tr. Am. Ophth. Soc. 46:218-243, 1948.

Case histories, physical findings, photographs, X-ray pictures and treatment of nine cases of dermoid of the orbit are presented. The incidence of dermoids and epidermoids is discussed and the similarity between the growths is stressed.

Elimination of the term epidermoid is advocated. The roentgenographic characteristic of these lesions is an area of diminished density with smooth regular margins of increased density. Proper roentgenography is essential for diagnosis. The plan of treatment rests upon the defect revealed. David Harrington.

Semadeni, B. **Tuberculous panophthalmitis.** Ophthalmologica 117:273, April-May, 1949.

A young man, released from a German concentration camp was admitted to a sanitarium at Davos with localized infiltrates in the right lung and at the hilus. Diffuse peritonitis and tuberculous meningitis were suspected. A few weeks after admission the patient developed an acute iridocyclitis in his left eye. Within a few days the iris became studded with yellow nodules. The disease took the course of tuberculous panophthalmitis. The patient died of tuberculous meningitis about three weeks after the onset of the iridocyclitis. The pathologic findings were typical.
                              Peter C. Kronfeld.

Wüst, K. **Treatment of imminent optic nerve atrophy due to retrobulbar hematoma and surgical access to the retrobulbar space.** Klin. Monatsbl. f. Augenh. 114:140-144, 1949.

The author describes a case of retrobulbar hematoma with bilateral amaurosis after traumatic compression of the thorax. The retrobulbar space was entered through the maxillary sinus with removal of the floor of the orbit. This approach is ideally suited for such hematomas which may occur in disease (scurvy, hemophilia, venous stasis) or may be due to trauma. The author's patient recovered completely. Proptosis and amaurosis disappeared at once. (References.)
                              Max Hirschfelder.

EYELIDS, LACRIMAL APPARATUS

Berke, R. N. An operation for ptosis utilizing the superior rectus muscle. Tr. Am. Acad. Ophth. pp. 499-518, May-June, 1949.

The author has modified the Motais operation. Through a conjunctival incision the superior rectus tendon is divided into three longitudinal tongues on each of which a suture is placed. The ends are inserted into the lid margin and tied. A buried chromic catgut suture is passed through the stump of the superior rectus tendon and through the superior rectus in its new position. A third set of four sutures is placed through the superior rectus in its altered position and then through the skin. A weakened superior rectus may be used, a smooth curve of the upper. lid is obtained, entropion is prevented, and the operation may be used on very young children but normal winking is interfered with, and lagophthalmus is present during sleep. The author performed his operation on 20 patients without failure and recommends it only where resection of the levator is contraindicated. (18 figures.) Chas. A. Bahn.

Berke, R. N. Congenital ptosis: a classification of two hundred cases. Arch. Ophth. 41:188-197, Feb., 1949.

A statistical study has been made of 200 consecutive cases of congenital ptosis seen at the Institute of Ophthalmology during the past fifteen years. There was a normal superior rectus muscle in 147, weakness of the homolateral superior rectus alone or combined with weakness of the homolateral inferior oblique in 34, the jaw-winking phenomenon of Marcus Gunn in 12, and ptosis associated with plepharophimosis in 7. The ptosis was unilateral in 145 and bilateral in 55, simple in 147 and complicated by hori-

zontal or vertical anomalies in 52. In 107 the levator muscle was active enough to justify resection of the muscle. In the others there was no such function and some modification of the Motais-Parinaud operation or the frontalis type of procedure was indicated. John C. Long.

Castresana y Guinea, Angel. Palpebral filaria. Arch. Soc. oftal. hispano-am. 9:293-305, March, 1949.

The literature is extensively reviewed and a case is reported. The presence of a filaria in the lower lid of a woman who became infected with the parasite in Guinea was recognized by its movements. It was pinched in a fold of skin with a forceps and surrounded with injected novocain. It became immobile and was then removed through an incision.

TUMORS

Forrest, A. W. Intraorbital tumors. Arch. Ophth. 41:198-232, Feb., 1949.

In a series of 222 cases of intraorbital tumor from the Registry of Ophthalmic Pathology which were studied histologically and clinically, 184 tumors were primary in the orbit; 93 were of mesenchymal origin, 48 related to the nervous system, 25 mixed tumors of the lacrimal gland and 18 were dermoids. Forty-four, or 24 percent, of the primary tumors were malignant. The 38 secondary tumors were 24 carcinomas, 6 neuroblastomas, 6 malignant melanomas, 1 retinoblastoma and 1 adenoma. Lipomas and dermoids were often anteriorly situated, and sarcomas, meningiomas, neurofibromas and gliomas were more frequently posterior and caused exophthalmos. Mixed tumors and hemangiomas were about equally divided between the two locations. Malignant mesodermal tumors, gliomas of the optic

nerve, hemangiomas and metastatic neuroblastomas occurred predominantly in youth and the tumors of the hematopoietic system and secondary carcinomas in more advanced age.   John C. Long.

Kambara, G. K. **Choroidal metastasis of a testicular chorionic epithelioma.** Arch. Ophth. 41: 587-598, May, 1949.

A case of a testicular chorionic epithelioma with metastases to the choroid of the right eye and in the brain, breast, stomach, intestine, liver, adrenal gland, subcutis, heart, lungs and pancreas is presented. Only three others in men and three cases of metastases to the choroid in women from chorionic epithelioma of the uterus have been reported.

Ralph W. Danielson.

O'Day, K. **Leiomyoma of the iris.** Brit. J. Ophth. 33:283-290, May, 1949.

Tumors of the iris are rare and all too often the oculist approaches the problem with a mind biased toward malignancy so that eyes are too often removed needlessly. A case of a benign leiomyoma of the iris is reported. These tumors can often be removed completely by an iridectomy and diagnostic biopsy is urged. Clinically these tumors appear as gray, vascular, sessile or pedunculated tumors, with little, if any pigment. They may be slow growing with periods of activity and may give rise to hyphema or even to cataract accomplicata and probably originate in an embryonal defect. (8 figures.)

Morris Kaplan.

Oravisto, Terttu. **Neurofibromatosis in the region of the eye.** Acta ophth. 27:89-98, 1949.

The literature is reviewed, and two cases reported in detail, including histologic data. The patients were four-year-old girls. One had a mass in the upper lid, and the other in the lower lid with thick-

ening of the adjacent tissues. One patient had congenital hydrophthalmos in one eye, and optic atrophy in the other. The other had no other ocular abnormalities. (2 figures.)   Ray K. Daily.

Pasca, G. **Two cases of chloroma orbitae; its hematocytoblastic origin and its treatment with ethylurethan and penicillin.** Boll. d'ocul. 28:101-109, Feb., 1949.

In two cases of chloroma of the orbit in children, aged 4 and 5 years, hemocytoblasts were found in the circulating blood as well as in the tumors. This seems to confirm the new hypothesis that chloroma is a form of hemocytoblastosis. In the girl, the disease involved both eyes while it was unilateral in the boy. The therapy mentioned in the title did not bring any improvement. (References.)

K. W. Ascher.

Silva, Daniel. **Errors of diagnosis in infantile intraocular tumors.** An. Soc. mex. de oftal. 22:217-236, 1948.

The author reports three cases. The chief cause of error is the appearance of a supposed tumor mass ("cat eye") diagnosed as glioma. In the author's first case the existence of marked photophobia was erroneously interpreted in spite of Terry's insistence upon the characteristic photophobic facies of children with retrolenticular fibroplasia, who automatically raise their hands to cover their eyes in the presence of light. In the second case too much importance was attached to hemorrhages, in spite of Reese's advice as to the frequent relation between fibroplasia and angiomatous processes. Excessive weight may be attached to the absence of prematurity at birth. The third case, in which the eye was not enucleated for glioma until invasion of the optic nerve was far advanced, emphasizes the necessity for using every possible means of diagnosis, including transillumination

under general anesthesia if necessary, and even enucleation and microscopic study of one eye. (9 figures, references.)

W. H. Crisp.

Soria. **Radium therapy in malignant epibulbar tumors.** Arch. Soc. oftal. hispano-am. 9:405-414, April, 1949.

On the basis of his experience with 17 patients, treated since 1929, Soria urges the application of radium-therapy for epibulbar malignant tumors which have not extended into the eyeball. He describes a method of application which consists in fixing with conjunctival sutures a tube 22 mm. in length and 2 mm. in diameter over the site of the tumor; over the tube is placed a lead shield 1 mm. in thickness, also fixed to the conjunctiva with sutures, through small perforations on its edges. The tube contains 5 mgm. of radium, and is left in place for 72 hours, with the patient in bed, and both eyes bandaged. The results were good in all but one patient. The side reactions of the irradiation were mild conjunctivitis, which healed in a few weeks, vascularization of the adjacent conjunctiva, which was obliterated by the application of a diathermy electrode, edema of the lids which disappeared spontaneously, and, in the eyes which were treated without the lead shield, a localized madarosis, the occurrence of which was eliminated by the shielding with lead. (2 figures, 4 photomicrographs.)

Ray K. Daily.

Souders, B. F. **Juxtapapillary hemangioendothelioma of the retina; report of a case.** Arch. Ophth. 41:178-182, Feb., 1949.

A case of von Hippel's angiomatosis retinae in a man, aged 40 years, is reported. The tumor, immediately adjacent to the optic nerve head, gave the preoperative impression of a malignant tumor of the optic nerve and the eye was enucleated. A detailed pathologic re-

port and photomicrographs are included.

INJURIES

Chavira, R. A. **Traumatic syndrome of the eye.** An. Soc. mex. de oftal. 22:113-130, 1948.

This is an 18-page thorough enumeration of various visual and other ocular effects arising from contusion of the eyeball. (References.)

W. H. Crisp.

Granstrom, K. O. **Extraction of non-magnetic intraocular foreign bodies.** Acta ophth. 27:47-58, 1949.

Fifteen extractions of non-magnetic foreign bodies are briefly described. In three the foreign body was situated in the anterior chamber, and the extraction was not difficult. Extraction of foreign bodies in the angle of the anterior chamber is greatly facilitated by X-ray control on the operating table and a T incision at the limbus. The precise location of the 12 foreign bodies in the vitreous or ocular wall was determined with a portable X-ray apparatus, and repeated X-ray photographs by the Larsson method, in which a point of a needle is imbedded in the exposed sclera over the previously determined site of the foreign body. The needle is moved and the roentgenogram repeated until the needle is shown exactly over the foreign body. A scleral flap, instead of radial incision, gives better access to the foreign body. In 3 of the 12 the author was successful.

Ray K. Daily.

Hill, J. C. **Visual manifestations of head injuries.** Canad. M.A.J. 60:464-468, May, 1949.

Most ocular abnormalities following head injuries are, 1. injury to the globe, 2. derangement of ocular motility, and 3.

lesions of visual pathways. This paper deals with lesions of visual pathways that occurred in World War II veterans seen at Christie Street Hospital Eye Clinic. Fifty-two cases of head injuries with ocular involvement were studied. In 25 cases disturbance of the optic nerve resulted in varying degrees of loss of visual acuity and optic atrophy. Fracture of the optic foramen was found in only four cases and only two lesions affecting the optic tracts were observed. In 25 cases the injury affected the optic radiation and visual cortex. There was marked loss of field with slight loss of visual acuity.

Theodore M. Shapira.

Stein, A. **The treatment of burns.** Ophthalmologica 117:232-237, April-May, 1949.

In the later stages of conjunctival and corneal burns, the author considers ischemic processes to be the predominant injurious factor. In order to alleviate this ischemia, he recommends the use of priscol in the form of constant eye baths. Twenty to 40 drops of the 10-percent priscol solution are added to 8 to 9 cc. of either artificial tears or blood plasma. This mixture is kept in contact with the cornea and conjunctiva by means of the rubber eye cup described in previous communications. A new feature has been added to this eye cup in the form of a heating device which keeps the solution at body temperature. The author reports good results in 10 cases of acid, lime and lye burns of the anterior surface of the eye. Peter C. Kronfeld.

Weber, E. **Simple procedure for the extraction of intracorneal wood splinters.** Ophthalmologica 117:238-239, April-May, 1949.

A splinter of wood penetrated the cornea more or less perpendicularly and no graspable portion protruded externally. For the extraction of such foreign bodies Weber recommends the following procedure. By careful dissection with a small Graefe knife, a small portion of the external end of the splinter is exposed. The tip of this Graefe knife is now introduced into the exposed portion, thereby securing the foreign body. With the aid of another Graefe knife introduced from the other side, the foreign body is extracted.

Peter C. Kronfeld.

Witmer, R. **The extraction of nonmagnetic intraocular foreign bodies.** Ophthalmologica 117:277, April-May, 1949.

The exact roentgenographic method of localization of intraocular foreign bodies by Goldmann and Bangerter (Ophthalmologica 101:139 and 215, 1941) has proved to be very helpful. The method is most suitable for foreign bodies which are situated close to the wall of the eyeball. After gross localization by means of lateral and antero-posterior X-ray examination, the scleral area closest to the foreign body is exposed surgically. A metal ring, 3 mm. in diameter, is attached to the sclera by means of fine barbs. A piece of dental film is placed right next to the ring and another X-ray picture is taken. The position of the ring is changed until the foreign body seems to be located in the center of the ring. Then the sclera is opened, and the choroid and retina carefully incised. The foreign body then either presents itself or can be found by feeling around "in the dark" with a small forceps. The remarkable thing about the report is that with this method of localization the final results of extractions on nonmagnetic foreign bodies are almost as good as those of magnetic foreign bodies.

Peter C. Kronfeld.

SYSTEMIC DISEASE AND PARASITES

Alpers, B. J., Foster, F. M., and Herbut, P. A. **Retinal, cerebral and systemic**

arteriosclerosis: a histopathologic study. Arch. Neurol. and Psychiat. 60:440-456, Nov., 1948.

The authors studied the retinal and cerebral vessels of 100 adults on whom autopsy was performed. Their findings are not in agreement with the general clinical impression that retinal arteriosclerosis is a sign of cerebral arteriosclerosis. Retinal arteriosclerosis merely indicates a 6 to 1 probability of cerebral arteriosclerosis, and absence of retinal arteriosclerosis does not exclude the presence of cerebral arteriorsclerosis.

R. Grunfeld.

Brand, I. **The ocular tension in myotonic dystrophy.** Orvosi Hetilap 12:376-380, 1949.

In a patient with myotonic dystrophy the tension of both eyes was strikingly low, especially on the side opposite the more atrophic testicle. The injection of antephysan resulted in a paradoxical response, namely increase of ocular tension. Hypotony is probably a frequent symptom in myotony. Gyula Lugossy.

Busacca, Archimede. **The green iridescent color of the intravitreal cysticercus.** Ophthalmologica 117:347-348, June, 1949.

Examination with the binocular ophthalmoscope of a typical intravitreal cysticercus revealed the iridescence of the cyst to be due to the presence of crystals in its walls. Peter C. Kronfeld.

Cass, E. E. **A case of ocular myiasis.** Brit. J. Ophth. 33:385-386, June, 1949.

Flies may lay their eggs in the conjunctival sac and some are dangerous as their maggots may burrow beneath the conjunctiva and even penetrate the globe. The case of a man who thought dust blew into his eye is presented. Severe pain with edema developed and eleven maggots were subsequently removed. The man

insisted that the maggots must have been in the cement mixture or the tap-water which was near and claims compensation.

Orwyn H. Ellis.

Dinger, G. **Observations in the fundus oculi in cases of pulmonary tuberculosis.** Klin. Monatsbl. f. Augenh. 114:105-107, 1949.

Almost 14 percent of 284 patients with pulmonary tuberculosis had fundus lesions. Nearly all patients had good central vision. The lesions were, for the most part, peripheral healed chorioretinitic scars. There were no patients with fresh lesions. (References.)

Max Hirschfelder.

Djacos, C. **The ocular symptoms of pellagra.** Ann. d'ocul. 182:279-294, April, 1949.

The author reports 41 cases of ocular lesion in an epidemic of pellagra. This disease results from a deficiency primarily of nicotinic acid, but also of other components of the B2 group. The most frequent ocular lesion was bilateral conjunctival edema with slight hyperemia. Corneal lesions were epithelial or interstitial. The former were characterized by a large number of fine, punctate epithelial opacities and depressions. The interstitial form usually involved the lower part of the cornea, and consisted of several deep nodules which had a tendency to ulcerate. Transient, faint, tongue-shaped opacities were observed in the lens. Night blindness was not an important symptom, nor were there retinal hemorrhages, papilledema, or neuritis. These lesions have been mentioned in the literature.

Chas. A. Bahn.

Doggart, J. H. **Diseases of the eye in relation to dental surgery.** Brit. J. Ophth. 33:338-347, June, 1949.

Developmental defects, trauma, and skeletal and endocrine diseases are

briefly reviewed because they offer many striking instances of associated dental and ocular disturbance. Eyes and teeth share susceptibility to a number of toxic hazards. The widespread theory of focal sepsis with teeth as the chief cause of ocular infection is vigorously attacked and ruthless dental extractions decried. Closer cooperation between the oculist and dental surgeons is urged.

Orwyn H. Ellis.

Fontana, Giuseppe. **Ophthalmoscopic examination of children with tuberculous meningitis and miliary tuberculosis, treated by streptomycin.** Arch. di ottal. 52:182-188, July-Aug., 1948.

Twenty patients, ranging in age from 9 months to 17 years, were observed ophthalmoscopically, some during treatment, with streptomycin, and others with streptomycin combined with a sulphonamide and vitamins A and D. Twelve had tuberculosis meningitis and eight had miliary tuberculosis in addition to the meningitis. In four there were no abnormal eye findings, in nine there was papilledema and in seven there was vascular stasis in the nerve head. In two of the last group miliary tubercles of choroid and iris tubercles were also present. In the nine with edema, marked regression of the edema was noted in 20 days, and two had normal papillae in 90 days. Those with vascular stasis in the papilla showed a greater resistance to treatment and persisted longer than others. This showed a direct relationship to the severity of the meningeal process. Miliary tubercles of the choroid indicated a general miliary tuberculosis. The manifestations of the nerve head and the choroid offered considerable information of value in the diagnosis and prognosis of these forms of tuberculosis.

Francis M. Crage.

Godtfredsen, E. **Pathogenesis of concurrent eye and joint diseases.** Brit. J. Ophth. 33:261-270, May, 1949.

An increasing awareness of an association between certain joint diseases both acute and chronic and eye symptoms along with increasing interest in allergies brings this report of study in Denmark. The list of acute joint diseases includes rheumatic fever, gonorrheal arthritis, simple urethritic polyarthritis (Reiter's disease) and uratic arthritis while the chronic diseases are Still's disease and ankylopoietic spondyloarthritis. In the first group eye symptoms were found in 2 to 80 percent, and in the second in 2 to 50 percent. These are in the main three groups of eye diseases namely: endogenous conjunctivitis, scleritis and episcleritis; iritis and iridocyclitis, and the sicca syndrome.

It is felt that most of the joint symptoms are an allergo-toxic reaction to a coccus, usually hemolytic streptococcus, or to a virus. It is supposed that the eye symptoms are a similar allergo-toxic phenomenon. This is borne out to some extent by histologic study. Concurrent disease in the heart, the skin and cavities lined with mucous membrane may also be significant.   Morris Kaplan.

González Aguilar, E. **The thesaurismoses.** An. Soc. mex. de oftal. 22:192-199, 1948.

These diseases are characterized by abnormal deposits of various substances in tissue cells such as Gierke's, Schuller-Christian's, Gaucher's, and Niemann-Pick's. (References.)   W. H. Crisp.

Magitot, A. **Congenital syphilis.** Ann. d'ocul. 182:306-312, April, 1949.

The changes of treatment and examination in syphilis during the past generation are reviewed. Retinal pigmentary degeneration and Leber's Disease are now known to have no relationship to congenital syphilis. Infection usually does not take place before the fifth month of intrauterine life because the embryo is not nourished directly by the mother's blood

until that time. Fewer fetal malformations are directly due to congenital syphilis than was thought. If the infection is virulent, the child is usually born dead and in approximately 30 percent, prematurely. Luetic infections tend to become less virulent with time. The positive Bordet-Wassermann test shows that maternal antibodies have been transmitted to the embryo, and disappears with the antibodies. Infection of the second generation is possible, but very rare. The symptoms may begin at birth or later. Iritis, choroiditis and cutaneomucous gummas are later manifestations. Dental changes, rickets, a tendency toward some infectious disease and endocrine anomalies are among the frequent evidences of congenital lues in youth. Medication should be continued until the patient is serologically negative. Trivalent arsenic and oil and soluble bismuth preparations are preferred to mercury in the treatment of the ocular symptoms of congenital syphilis. The use of penicillin is experimental.

Chas. A. Bahn.

Rosen, Emanuel. **The significance of ocular complications following vaccination.** Brit. J. Ophth. 33:358-368, June, 1949.

The literature on ocular complications following vaccination and also on post-vaccinial encephalitis is reviewed and six case reports are presented. Ocular complications developing within a specific period after vaccination are part of a post-vaccinial ocular syndrome which may consist of interstitial keratitis, central serous retinopathy and cranial nerve involvement. Cases illustrating activation of previously existing conditions are presented. The pathologic picture of post-vaccinial encephalitis and the encephalitis of the acute exanthemata are identical. The author points out many characteristics of this condition which may ultimately be explained on an allergic basis.

Orwyn H. Ellis.

Smith, Mary D. **Diabetic neuropathy with Argyll Robertson pupils: report of two cases.** Glasgow Med. J. 30:181-184, May, 1949.

The neurologic complications of diabetes mellitus are reviewed. In one series of 3,000 diabetics two had this complication and in another series of 19,000 only 10 had Argyll Robertson pupils. The first patient with severe diabetes had small irregular pupils that did not react to light but did react in accommodation. The iris was atrophic and there were lens opacities and retinal exudates and hemorrhages. The deep tendon reflexes were absent in the legs and diminished in the arms. Under treatment for diabetes the superficial and deep reflexes in the legs returned to normal. The pupillary reflexes did not change. The other patient displayed similar manifestations. The causes for the appearance of neurological changes in diabetes are reviewed.

H. C. Weinberg.

Wilson, W. A. **Temporal arteritis with report of a case.** Ann. West. Med. and Surg. 3:177-179, May, 1949.

Arteritis complicated an otherwise normal cataract extraction and recurring hemorrhages and secondary glaucoma followed. An inflammation of the adventitia of the vessel spreads to the media where focal necrosis and giant cell reaction occur. The intima becomes thickened but is not otherwise affected.

CONGENITAL DEFORMITIES, HEREDITY

Briggs, A. H., and McLean, D. W. **An unusual congenital defect.** Brit. J. Ophth. 33:381-384, June, 1949.

A mass present in the anterior chamber and adherent to the posterior corneal surface in one quadrant and apparently of mesodermal origin, was seen at birth. Vessels were present on its anterior sur-

face. There was an anomalous distribution of the vessels of the optic disc. The condition was unchanged at six years of age and no useful vision was found.

Orwyn H. Ellis.

Cuendet, J. F., and Della Porta, V. Hereditary nystagmus. Ophthalmogica 117:199-201, April-May, 1949.

The report deals with a family of 106 members, 22 of whom were affected with typical congenital (hereditary) nystagmus. The mode of transmission was dominant and sex-linked.

Peter C. Kronfeld.

Franceschetti, A., and Maeder, G. Cataract associated with skin lesions of the poikiloderma and scleroderma type. Ophthalmologica 117:196-198, April-May, 1949.

On the basis of a review of the literature, the authors give a detailed description of the two hereditary diseases indicated in the title. The association of cataract with skin lesions of the type of poikiloderma atrophicans vasculare is known as Rothmund's disease. The skin lesions develop during the first year of life, often in the form of one eruption, and are characterized by patchy hyper- and hypopigmentation, telangiectasis and atrophy, preceded in places by true vesicles. Nails and hair are also affected. The skin lesions reach a standstill in early childhood. Cataracts of the endocrine type make their appearance between the ages of two to six years. Hypoplasia of the ovaries or testes is the characteristic endocrine manifestation of this disease. The affected individuals are of normal height and mentality. The disease is hereditary, the mode of transmission probably recessive. Franceschetti and Maeder have found 20 cases of this disease in the literature.

Scleroderma associated with cataracts is known as Werner's syndrome. Here again the basic anomaly appears to be genital hypoplasia, of a higher degree, however, than in Rothmund's disease. The skin lesions are progressive and recurrent. The disease is also hereditary, and more common in men than in women. The authors have found 42 cases of this disease in the literature.

Peter C. Kronfeld.

François, J. Familial dermochondrocorneal dystrophy. Ann. d'ocul. 182:409-442, June, 1949.

The author reports the first two cases of this rare dystrophic syndrome in siblings. In an otherwise normal boy, aged 11 years, and his 12-year-old sister, the several constitutional degenerative processes became manifest after birth. They had numerous bilateral, symmetrical, subepithelial corneal opacities of different sizes and shapes, deformities of the epiphyses of the metacarpal and tarsal bones, and numerous xanthomas on the fingers, nose, and ears. The differentiation from several types of corneal, osteochondral and lipid genetic abnormalities is briefly discussed. The disease in these siblings resembled dysostosis multiplex.

Chas. A. Bahn.

Heatley, Juan. Congenital familial miosis. An. Soc. mex. de oftal. 22:141-148, 1948.

A family tree of 5 generations and 30 individuals is presented. Nine were investigated, trustworthy data were obtained on 10, and the condition of 11 was unknown. Seven subjects had congenital miosis which was associated with microcornea in three, 11 had myopia, and three had increased tension. The defect was not pure hereditary and congenital miosis, but a series of four changes which seemed irregularly mixed, transmitted dominantly, and, except the tension, present from childhood. Paraipan, C. **Bilateral anophthalmos.** Ann. d'ocul. 182:214-215, March, 1949.

The author examined an otherwise normal new-born girl with no traceable hereditary tendency to ocular defects who had microblephary and almost complete absence of both eyeballs. This rarity is ascribed to maldevelopment of the optic vesicle.   Chas. A. Bahn.

Straub, Wolfgang. **Congenital anterior synechia of the pars retinae of the iris.** Klin. Monatsbl. f. Augenh. 114:211-213, 1949.

A patient exhibited a brown tubular strand of tissue which originated behind the iris, penetrated the anterior chamber and was inserted in a gray area in the endothelium of the cornea. It is believed that this was caused by a damage of the corneal endothelium during early intra-uterine life resulting in an adhesion between the pars retinae of the iris and the endothelium corneae at a time when the cavity of the optic vesicle was still open. Fanta, H. **Causes of blindness in the young.** Klin. Monatsbl. f. Augenh. 114:219-224, 1949.

Among the 90 pupils of the Vienna School for the Blind there were 15 with partial and 75 with total blindness. Nearly one half of the partially blind had congenital cataract and most of them had

been operated on. Of the total blindness 20 percent resulted from injury, 14 from retinal degeneration, 9 from cataract, 9 from atrophy of the optic nerve, 7 from brain tumor and 5 from glaucoma. The blindness due to ophthalmia neonatorum was only 3 percent. Max Hirschfelder.

Hruby, K. **Urgent conditions in the eye.** Wien. klin. Wchnschr. 61:337-341, June 3, 1949.

This lecture was given to a group of general practitioners to point up the conditions in the eye which threaten vision. Symptoms seemingly unimportant to the patient, such as contraction of the field and slowly progressive loss of vision, beginning lid epithelioma, and lagophthalmos must be recognized as serious by the physician who first sees them. Vaccination blepharitis, diphtheria and gonorrhea are extremely serious. The practitioner should learn to differentiate ciliary from conjunctival injection and recognize the significance of each. Hruby describes the first-aid measures the general practitioner should employ in acute iritis and in chemical and perforating injuries. He discusses in detail the early recognition of glaucoma and the importance of not mistaking it for senile cataract. He points out how important early operation is in retinal detachment. Finally, amblyopia ex anopsia may lead to loss of vision and glasses should therefore be prescribed early after congenital cataract operation and in strabismus. Myopia and hyperopia in the child need correction only if they are very severe.   B. T. Haessler.

Kuhn, H. S. **A manual on toxic hazards.** Tr. Am. Acad. Ophth. pp. 595-596, May-June, 1949.

This manual, which has recently been published, is the result of two years' effort by the Joint Committee on Industrial Ophthalmology, and was made possible by the National Society for the Preven-

tion of Blindness. The first section deals with tests, protective means and similar data pertaining to industrial ophthalmology. In the second section, a preliminary report of ocular toxic chemicals is presented in detail. The scientific and trade names are given as well as the symptoms and chemical effects. In the third section a description of the accepted emergency first aid procedures in treatment of chemical eye injuries is reported in detail. This manual should be in the office of every ophthalmologist.   Chas. A. Bahn.

Uribe Troncoso, Manuel. **The fiftieth anniversary of Anales de Oftalmologia.** An. Soc. mex. de oftal. 22:205-207, 1948.

Uribe Troncoso, in association with Daniel M. Vélez, established the Anales in July, 1898, to promote the development of ophthalmology in Mexico. It was the only periodical publication in the Castilian language devoted to ophthalmology. The printing was at first undertaken by a department of the Mexican government and other expenses were borne by the founders. Then it was the official organ of the Mexican Ophthalmological Society and still is. Five or six years later Menacho of Barcelona, Spain, and Santos Fernández of Cuba started in the Spanish (Castilian) language the Archivos de Oftalmologia Hispano-Americanos and proposed combining the two journals under an editorial office in Barcelona. This invitation was rejected. After fourteen years the Mexican revolution of 1910 caused suspension of the Anales, and in 1916 Uribe Troncoso left Mexico and settled in New York. After the years of social depression the Anales was continued in Mexico by Daniel Vélez.

NEWS ITEMS

News items should reach the editor by the 12th of the month but, to receive adequate publicity, notices of postgraduate courses, meetings, and so forth should be received by the editor at least three months before the date of occurrence.

DEATHS

Dr. Ira Bradford Chadwick, Coffeyville, Kansas, died June 16, 1949, aged 79 years.

Dr. John M. Robinson, Goshen, New York, died June 24, 1949, aged 79 years.

Dr. Milton J. Stern, Lexington, Kentucky, died June 12, 1949, aged 59 years.

ANNOUNCEMENTS

AOS TRANSACTIONS

The 1949 Transactions of the American Ophthalmological Society, published in book form, may be purchased by advance subscription. Containing the scientific papers given at the annual meeting and the theses for membership, this volume may be ordered from the editor:

Dr. Wilfred E. Fry
1930 Chestnut Street
Philadelphia 3, Pennsylvania

The price is $12.00, and all orders must be received by December 1, 1949.

GILL GRADUATE COURSE

The 23rd annual spring graduate course of the Gill Memorial Eye, Ear, and Throat Hospital, Roanoke, Virginia, will be held April 3 to 8, 1950. The course is open only to qualified practitioners who are giving full time to their specialty. The hospital reserves the right to reject any application.

On the guest faculty will be the following: Dr. F. W. Stocker, Durham, North Carolina; Dr. Conrad Berens, New York; Dr. Fred Wilson, Chicago; Dr. C. W. Mayo, Rochester, Minnesota; Dr. Edmund B. Spaeth, Philadelphia; Dr. Arthur J. Bedell, Albany, New York; Dr. James J. Regan, Boston; Dr. W. Gayle Crutchfield, Charlottesville, Virginia; Dr. Stuart Cullen, Iowa City, Iowa; Dr. Richard G. Scobee, St. Louis; Dr. Daniel S. Cunning, New York; Dr. Alson E. Braley, New York; Dr. Karl M. Houser, Philadelphia; Dr. Hugo L. Bair, Rochester, Minnesota; Dr. Gabriel Tucker, Philadelphia; Dr. Edward M. Walzl, Baltimore; Sir Alexander Fleming, London; Dr. J. Barrett Brown, St. Louis; Dr. Walter B. Hoover, Boston; Dr. Oscar O. Hansen-Pruss, Durham, North Carolina.

HISTOPATHOLOGY COURSE

The schedule of the three-month course in "Histopathology of the Eye," given by Dr. Brittain F. Payne and associates at the New York Eye and Ear Infirmary has been rearranged to last one week in January, 1950.

The course will be given in the afternoons of the second week in January, and will consist of the same number of hours of instruction and material as previously allotted. The dates are from January 9th to 14th, and further information may be obtained by writing the Post-Graduate Division of the New York University College of Medicine.

WILLS HOSPITAL CONFERENCE

The annual clinical conference of the Wills Eye Hospital will be held in Philadelphia on Friday and Saturday, March 17 and 18, 1950.

Dr. Francis Heed Adler will deliver the annual Arthur J. Bedell Lecture on the evening of March 17th.

MEXICAN MEETING

From November 6th to 12th, the Association to Eradicate Blindness in Mexico will have its fourth biannual meeting. Further information may be obtained by writing the secretary, Dr. Ramón Olivera López, Gomez Farias 19, Mexico, D.F.

RESERVATIONS FOR FLORIDA MEETING

The National Society for the Prevention of Blindness will hold a five-day conference in conjunction with the interim session of the Pan-American Association of Ophthalmology, March 26 to 30, 1950, at the Floridian Hotel, Miami Beach, Florida. The theme of the meeting will be "The Americas Unite to Save Sight," and among the subjects to be discussed are: Current blindness prevention programs in countries of the Western Hemisphere; Trachoma; Industrial ophthalmology; Eye problems of school children; Medical and social management of the glaucomas.

Persons directly or indirectly concerned with eye health and safety will find this conference of interest. Details concerning the program may be obtained by writing directly to the National Society for the Prevention of Blindness, 1790 Broadway, New York 19.

Reservations should be made in the near future with the Floridian Hotel, 540 West Avenue, Miami Beach, Florida.

GRANTS-IN-AID OFFERED

The National Council to Combat Blindness, which was established for the purpose of financing and stimulating ophthalmological research, is now offering grants-in-aid to scientific investigators. Applications to be considered for the first group of awards should be in the office of the council by February 15, 1950. Application forms may be obtained by ad-

dressing: Secretary, National Council to Combat Blindness, Inc., 1186 Broadway, New York 1, New York.

SOCIETIES

ORTHOPTIC TECHNICIANS PROGRAM

On October 10th and 11th, at Chicago, the American Association of Orthoptic Technicians held its eighth annual meeting. On the program were:

"Anomalous retinal correspondence: Its essence and its significance in diagnosis and treatment," Dr. Hermann M. Burian, Boston; "Orthoptics in relation to preoperative training," Mrs. Elsie Laughlin, Iowa City, Iowa; "Physiology of vision," Miss Ann Stromberg, Boston; "Standards for vision," Miss Ruth McNab, Detroit; "Treatment of amblyopia," Miss Martha Peterson, Columbus, Ohio; "Types of occlusion and results," Miss Ruth Fisher, Denver; "Differentiation of Phi phenomenon and parallax and use of Phi phenomenon in determination of retinal correspondence," Miss Dorothy Franklin, Beverly Hills, California (with a discussion by Dr. S. Rodman Irvine, Beverly Hills); "Orthoptics in relation to postoperative training," Miss Frances Fowler, Seattle; "Orthoptic suggestions," Miss Eva DeMars, Philadelphia; "Stimulus-response mechanisms in binocular coördination," Dr. Edwin F. Tait, Norristown, Pennsylvania (with a discussion by Miss Electra Healy, Chicago); "Anomalous correspondence," Miss Marjorie Enos, New York (with a discussion by Dr. Michel Loutfallah, Santa Barbara, California); "The accommodative effort syndrome," Dr. Robert Hill, Portland, Oregon (with a discussion by Mrs. Louise Wells Kramer, Washington, D.C.).

PENIDO BURNIER OFFICERS

The Medical Association of the Institute Penido Burnier, Campinas, Brazil, has elected the following officers for 1949-1950; President, Dr. Penido Burnier Filho; 1st secretary, Dr. Alfonso Ferreira Filho; 2nd secretary, Dr. Alfredo Martinelli; historian and treasurer, Dr. Leôncio de Souza Queiroz; directors, Dr. Guedes de Melo Filho, Dr. F. J. Monteiro Sales, and Dr. José Martins Rocha.

CENTRAL ILLINOIS SOCIETY

The next meeting of the Central Illinois Society of Ophthalmology and Otolaryngology will be held at the Abraham Lincoln Hotel in Springfield, Illinois, on November 18th, 19th, and 20th. Dr. William L. Benedict of the Mayo Clinic will give lectures on: "Cataracts and systemic diseases," "General diseases: Ocular manifestations," and "Tumors of the eye and orbit."

Dr. H. P. House, associate professor of otolaryngology at the University of Southern California, will speak on: "Indications and end results of fenestration surgery," "Management of otitis media," and "Management of the continually stuffy nose."

Dr. Walter E. Owen, Peoria, Illinois, a member of the society will speak on: "Drug therapy in respiratory allergy." Dr. Herbert M. Kobes, director of the University of Illinois, Division of Services for Crippled Children, will speak on the "State of Illinois coöperates with the ophthalmologist and otolaryngologist."

HAWAII SOCIETY PROGRAM

The Hawaii Eye, Ear, Nose and Throat Society held its opening fall meeting at Tripler General Hospital, Honolulu, Territory of Hawaii, on September 15th.

A paper on "An evaluation of methods of treatment in 155 cases of pterygium" was presented by Lieut. Col. John H. King, Jr. (MC), chief of EENT section, Surgical Service, Tripler General Hospital. His talk was illustrated by descriptive slides on cases of pterygium and on various operations performed during the past 12 months. The presentation was discussed by Dr. Forrest J. Pinkerton, Dr. Ogden D. Pinkerton, Dr. H. F. Moffat, and Dr. Philip M. Corboy. Maj. Aubrey K. Brown (MC), assistant chief of EENT section, presented a case report on "Esophageal stenosis." His paper was discussed by Dr. John P. Frazer, Dr. L. Q. Pang, and Dr. Clarence J. Kusunoki.

TORONTO REFRESHER COURSE

The Faculty of Medicine of the University of Toronto offers a combined refresher course in ophthalmology and otolaryngology from January 9 to January 14, 1950.

The otolaryngological subjects will be presented during the first three days of the course and the ophthalmological subjects during the last three days. Lectures and surgical clinics in both subjects will be given by outstanding guest speakers as well as by members of the Faculty.

Guest speakers in otolaryngology will be: Dr. W. J. McNally, Montreal, and Dr. Henry Orton, Newark, New Jersey; in ophthalmology: Dr. P. C. Kronfeld, Chicago, and Dr. J. A. MacMillan, Montreal.

The course will be given for a minimum of 10 students and a maximum of 20 students. The fee for all or any part of the course will be $100.00, payable to the chief accountant, Simcoe Hall, University of Toronto. Application should be made to the Dean of the Faculty of Medicine, not later than November 30, 1949.

GLASGOW AUTUMN TERM

During October a series of meetings are being held in the Department of Ophthalmology, University of Glasgow. On October 5th, Dr. George Leaf presented a paper on "Biochemical aspects of methanol poisoning," and on October 12th, Dr. W. O. G. Taylor spoke on "Control of clotting in ophthalmology." "Tobacco amblyopia," is the subject Dr. R. Leishman presents on October 19th. Dr. A. Wright Thomson will speak on "Cyrate atrophy of the choroid" on October 26th. At each meeting, discussion will follow the presentation of the main paper.

CONTENTS

THE DIAGNOSIS AND TREATMENT OF OCULAR ALLERGY*

ALAN C. WOODS, M.D.

Baltimore, Maryland

The proper diagnosis and treatment of ocular allergy require a clear concept by both the ophthalmologist and the allergist of the relation of hypersensitivity to inflammations of the external eye and uveal tract, of the specific allergens most frequently responsible for the hypersensitive state, and of the methods for detecting and treating such hypersensitivity. Much of our knowledge on these points is fragmentary and there are great gaps where little or nothing is known. In this paper, the effort is made to outline the broad principles of ocular allergy as we now understand them and to describe the methods of diagnosis and treatment usually accepted at the present time.

Allergic reactions in the eye are dependent upon an underlying hypersensitivity to a specific antigen and contact of this antigen with the sensitized cells. The underlying hypersensitivity may be either of the anaphylactic and pollen type or of the bacterial type.

The anaphylactic and pollen types of hypersensitivity are caused exclusively by proteins or by the combination of nonprotein substances (such as drugs or metals) with the native protein of the host, thus forming a new compound which acts as a foreign protein. In the anaphylactic and pollen types of hypersensitivity the reactions of the sensitized cells to contact with the specific antigen is an immediate one, is characterized by an urticarial weal, a contraction of smooth muscle, and increased capillary permeability. It is believed due to the liberation of histamine or a histaminelike substance. The anaphylactic reaction does not in itself cause actual damage to the cells. However, after repeated local anaphylactic reactions an Arthus phenomenon may occur. This is the occurrence of local necrosis and is due not to a direct toxic action on the cells, but to thrombosis and rupture of the nutrient vessels.

The hypersensitivity of infection is also known as bacterial hypersensitivity or the tuberculin type of hypersensitivity. It is produced only by the parenteral contact of the tissue with the living or dead bacterial body or filterable viruses. It cannot be produced by the soluble proteins of the organisms, but once the hypersensitivity is produced by the bacterial body, reactions can be elicited by the soluble specific proteins. When tissues with the bacterial type of hypersensitivity come into contact with the specific bacterial antigen or its soluble products, the allergic reaction is delayed, coming on in 24 to 48 hours. The reaction in bacterial allergy causes actual damage to the cells, in severe cases actual death and necrosis. The cause of this cell damage is not clear—it is variously believed that the antigen-antibody union produces a toxin which damages the cells, or that the cell damage is the result of some enzymelike action.

CLINICAL ALLERGIC REACTIONS

The various clinical allergic reactions in the eye may be classified as follows.

A. CONJUNCTIVA

Four types of allergic reactions are recognized in the lids and conjunctiva:

1. *A sudden, edematous type of reaction,* affecting primarily the conjunctiva alone, characterized by a glassy edema of the conjunctival fold, marked congestion of the palpebral and bulbar conjunctiva with profuse lacrimation, sudden in its onset, and sudden in its disappearance.

The classic example of this type is the conjunctivitis associated with hay fever and asthma. This is a typical pollen-type hypersensitivity. The mucous membrane of the eye participates in the general hypersensitivity of the mucous membranes of the upper respiratory tract and like them reacts with a sudden inflammatory edema when in contact with the specific sensitizing substance, the air-suspended allergens. There is usually chemosis of the palpebral and bulbar conjunctiva, profuse lacrimation, and a nonpurulent secretion without bacteria. The reaction usually subsides quickly after the instillation of epinephrine hydrochloride.

2. *Eczematous, edematous type of blepharoconjunctivitis.* The lids are swollen with a firm edema, the margins are inflamed, the skin of the lids has a characteristic, dry, eczematous feeling, the palpebral conjunctiva is congested; there is usually a slight chemosis. There is profuse lacrimation. The most frequently observed example of this type of allergic reaction is that due to drug sensitivity, atropine, butyn, and other alkaloids. As already stated, the drug, *per se,* is not believed to be the offending allergen, but a combination of the drug with the native protein, forming a new specific allergen which is foreign to the host.

3. *Chronic or recurrent irritative conjunctivitis.* Often this is associated with a slight marginal blepharitis. Subjectively, the most pronounced symptoms are a sensation of dryness and itching. Objectively, there is usually a slight or moderate congestion of the palpebral conjunctiva, often with small patches of dry folliculosis and no chemosis. A low-grade irritative marginal blepharitis, usually without crusts of any cutaneous reaction, may be present. The allergens responsible for the underlying sensitivity may be bacterial, notably staphylococcus toxin, or the various epidermals, inhalants, animal dusts, and so forth.

4. *Vernal catarrh.* The clinical picture is almost characteristic, with seasonal occurrence, lacrimation, itching, conjunctival congestion, with large follicles over the palpebral, and occasionally on the bulbar conjunctiva. In the latter stages, these assume the appearance of large "cobblestone" follicles with irregular distribution.

The evidence in favor of an underlying allergy as the predisposing cause is the seasonal occurrences of the attacks, the tendency of the disease to attack the young, the comparative absence of bacteria in the secretions, the usual abundance of eosinophiles in the discharge, the specific hypersensitivity to various allergens so often demonstrated, and the general allergic diathesis of many of the patients.

B. CORNEA

Two types of superficial keratitis are believed to be allergic in origin—phlyctenular keratoconjunctivitis and recurrent marginal ulcers. It is quite possible that various other forms of superficial keratitis may be on an allergic basis, or their course influenced by a concomitant hypersensitivity of the corneal epithelium to bacteria or filterable viruses.* However, as a rule, such relationship is so tenuous or hypothetical that from the practical standpoint it is of little concern.

It is also undeniably true that the course of certain forms of deep keratitis (notably tuberculous keratitis and the nummular keratitis sometimes seen in chronic brucellosis) is profoundly influenced by the degree of specific local sensitivity present in the

---

* Such as recurrent corneal erosion after minor corneal trauma and infection.

cornea. The problem here, however, is identical to that of similar endogenous infections of the uveal tract and the same principles which influence them would govern corneal lesions. These will be discussed later.

1. Phlyctenules. The well-known clinical picture requires little comment. The onset is usually acute, small millet-seed nodules froming on the cornea and occasionally on the adjacent conjunctiva, usually at or near the limbus, the phlyctenules being surrounded by a zone of local inflammation. A grayish crater soon forms at the apex, absorption is rapid, and the small ulcer so formed epithelizes over rapidly, usually leaving little trace. They frequently occur in small showers, and recurrences are common.

The allergic basis of phlyctenules appears clearly established. Phlyctenules in both man and experimental animals have been produced by the instillation of tuberculin in the conjunctival sac, and by the instillation of other specific sensitizing allergens. Tuberculoprotein is the allergen commonly incriminated, and, in children suffering with phlyctenulosis, a high degree of tuberculin hypersensitivity can usually be demonstrated, and likewise a history of exposure to open tuberculosis. Various other allergens have from time to time been incriminated. The diagnosis offers no difficulty.

2. Marginal ulcers. These begin as small infiltrates, near the limbus. they rapidly break down and form small pinhead ulcers, often in a crescent around the limbus. There is associated hyperemia. The tendency is to rapid healing without deep penetration. Itching and irritation are marked. Recurrences are common. They occur frequently in elderly people and may follow a catarrhal conjunctivitis. Low-grade foci of infection, in the sinuses, tonsils, and so forth, are frequently found.

The evidence that these ulcers are allergic is largely circumstantial and not altogether conclusive. Cultures of the ulcers are usually sterile. The patients usually show evidence of bacterial hypersensitivity and the presence of remote foci of infection. A concomitant or preceding low-grade conjunctivitis is the rule oftener than not. The fact that they occur characteristically near the limbus has given rise to the supposition that the intoxicating bacterial allergens may reach the sensitized corneal epithelium at the limbus from the adjacent vascular bed. The patients usually do well on specific desensitization and recurrences can, as a rule, be controlled. On these grounds, and the inability to find any other concrete cause to explain them, this type of marginal ulcer is usually regarded as an example of bacterial allergy.

C. UVEAL TRACT

Allergic reactions of the uveal tract may be classified as follows: (1) Inflammations related to a hypersensitivity from absorption of the native organ specific proteins of the eye, uveal pigment and lens protein (sympathetic ophthalmia and endophthalmitis phacoanaphylactica) ; (2) nongranulomatous uveitis due *per se* to a bacterial hypersensitivity; (3) granulomatous uveitis due to the direct invasion of the ocular tissues by specific living pathogens, in which the course and character of the lesion is influenced by tissue hypersensitivity.

1. a. Sympathetic ophthalmia. The assumption of an allergic phase in sympathetic ophthalmia is based upon an abnormal reaction to uveal pigment, developed by the body cells either before the outbreak of the disease or early in its course.

The pigment of the uveal tract possesses the immunologic quality of organ specificity and lacks species specificity—in short, it is potentially able to act as a foreign protein in the homologous animal.

The abnormal reaction to uveal pigment may be demonstrated by injecting small amounts of uveal pigment in the skin. The results are epithelioid, and lymphocytic infiltration about the injected pigment and phagocytosis of the pigment occur—a picture comparable to the histologic picture of

sympathetic ophthalmia in the eye.

This hypersensitive reaction to pigment does not, however, appear to be the cause *per se* of the disease for it may be present in some individuals with posttraumatic and postoperative uveitis without sympathetic disease. It apparently sets the stage for the outbreak of the disease and determines its pathologic and histologic pattern.

Other, as yet unknown, and possibly quite nonspecific factors, may be responsible for the actual causation or outbreak of the disease, once the stage is set by the development of pigment hypersensitivity. The development of cutaneous hypersensitivity to uveal pigment after any traumatism or operative insult to the uveal tract of the eye is therefore a cause for alarm and increased vigilance.

1. b. Endophthalmitis phaco-anaphylactica. This is a term applied to an endogenous inflammation of the uveal tract, supposed to be dependent on the development of a hypersensitivity to lens protein, and the further absorption of lens protein by the sensitized tissues. It has been abundantly demonstrated that some of the proteins of the lens are organ specific and lack species specificity and are thus potentially capable of acting as foreign proteins. It is also recognized that an inflammatory reaction may follow the absorption of lens protein.

There has, however, been considerable question of the allergic or anaphylactic nature of this recognized clinical disorder, many observers pointing out the weak antigenic action of lens protein and attributing the delayed inflammation which follows its absorption to an inherent toxicity of the material, to a low-grade infection, or to both.

The weight of evidence, however, indicates there is an actual hypersensitivity to lens protein in individuals with this type of ocular reaction. The development of the hypersensititive state may be related to the synergistic actions of toxins absorbed from some remote focus of infection or an actual low-grade infection in the eye, such a factor enhancing the antigenic activity of the lens protein and producing the hypersensitive state. Further evidence that this is a clinical entity are the therapeutic results which follow proper desensitization procedures.

2. Nongranulomatous uveitis. The nongranulomatous uveitis resulting from a bacterial hypersensitivity is dependent upon a prior infection with the specific bacteria. The original infection may have been in the eye, in which case the ocular tissues are especially reactive; or it may have been a systemic infection, the eye participating in the general tissue reaction. Once this hypersensitive state has been established, an allergic inflammatory reaction may be elicited either by contact of the sensitized cells with the soluble bacterial protein, as in the case of ocular focal reactions produced by tuberculin, or by direct contact with the living or dead bacterial body, as in the case of the experimental "ophthalmic reaction."

Nongranulomatous uveitis in the anterior uvea is characterized by an acute onset, with marked ciliary congestion, photophobia, and lacrimation. The inflammatory changes in the iris are usually limited to loss of luster, blurring of the normal iris pattern, and dilatation of the capillaries. There is frequently a gelatinous or fibrinous exudate in the anterior chamber. The keratitic precipitates are usually small, pinpoint in type, and composed chiefly of lymphocytes. The course is stormy but usually brief, and the eyes recover with amazingly few residua. After repeated attacks, however, organic changes may take place in the eye, with synechia and organized exudates, and the eyes assume the picture of the granulomatous form of the disease. The destructive changes which occur after repeated attacks of nongranulomatous uveitis may possibly be interpreted as an Arthus phenomenon.

In the posterior uvea, the nongranulomatous uveitis is not so characteristic. In general, the eyes show only slight blurring of the vitreous; there are no discernible exu-

dates, but there is marked subretinal edema, blurring the elements of the fundus pattern.

Nongranulomatous uveitis is seen, in its' purest form, in the iritis and uveitis associated with rheumatoid arthritis or with old gonococcal infections. The supposition is that, at the time of a former bacteriemia, the eye has been invaded by the organisms. These bacteria have been destroyed by the normal bactericidal action of the ocular fluids but, as a result of the ocular invasion and parenteral contact of the tissues of the eye with the organism, there has been left behind a hypersensitivity of the uveal tract. Any later contact of this sensitized ocular tissue with the specific organism or its products, brought to the eye either by a later chance transient bacteriemia or by absorption of the bacterial products from a focus of infection, or, indeed, from a normal cutaneous or mucous membrane surface, results in a sudden, sharp, allergic reaction. The underlying sensitivity is probably of the bacterial type, although there may be an anaphylactic type of sensitivity to the hapten or polysaccharide fraction of the invading organisms.

3. Granulomatous uveitis. The underlying cause of granulomatous uveitis is an actual invasion of the uveal tract by the causative organisms in their living form. Granulomatous uveitis may be caused by tuberculosis, syphilis, brucellosis, sarcoidosis, toxoplasmosis, virus diseases, and quite probably by other as yet unidentified agents.

The clinical picture of granulomatous uveitis is quite different from that of nongranulomatous uveitis. The onset is usually insidious; the inflammatory reaction is not unduly severe. Organic changes occur in the iris with edema of the iris stroma, often localized thickening or felting of the iris, and frequently with actual nodules or tubercles. There is a marked tendency to the formation of posterior synechias and greasy exudates over the anterior capsule of the lens. The keratic precipitates are usually heavy, of the mutton-fat variety, and are composed chiefly of epithelioid cells. Small accumula-

tions of epithelioid cells may occur on the pupillary border or over the surface of the iris, the so-called Koeppe and Busacca nodules. In granulomatous disease of the posterio uvea, the characteristic picture is heavy vitreous opacities and actual exudates, with more or less associated subretinal edema.

The influence of a hypersensitivity in granulomatous uveitis is best illustrated by the tuberculous form of the disease, where the question has been extensively studied. While the injection of tuberculin and other fractions of the tubercle bacilli will produce pure allergic reactions in sensitized tissue, the progressive tuberculous lesions with cellular infiltration, tubercule formation, tissue necrosis, and caseation or encapsulation are produced only by the actual invasion of the tissues by the tubercle bacillus.

The acute inflammatory phases of the lesion with tissue destruction, caseation, and necrosis are dependent largely upon tissue hypersensitivity to tuberculoprotein. If there is no restraining immunity, the tubercle bacilli spread rapidly and first produce hard tubercles. Thereafter, tissue hypersensitivity to tuberculoprotein develops, and with this there is acute inflammation, and lastly, necrosis, and caseation. If the spread and multiplication of the bacilli is restrained by the forces of immunity, the development of tissue hypersensitivity is slight.

The character of a tuberculous lesion is therefore largely dependent upon the balance of immunity and tissue hypersensitivity present. The other factor is, of course, the number and virulence of the invading bacilli. With this last factor a constant, circumscribed, rapidly encapsulated lesion should be regarded as an indication of high immunity and low tissue hypersensitivity; while spreading, destructive lesions are dependent upon a low immunity and high tissue hypersensitivity. Lesions midway between these two extremes are dependent upon the varying balance of these two factors.

The therapeutic indications based on this

concept of the pathogenesis of tuberculous lesions are obvious. The invading bacilli may be attacked by the chemotherapeutic and antibiotic agents which have a specific action on the tubercle bacillus. All possible efforts should be made to achieve any possible enhancement of immunity and the fatal tissue hypersensitivity should be abolished. This latter can be done only be desensitization with tuberculin.

It is quite probable that allergy may play an equal role in other forms of granulomatous uveitis, although this is as yet unproved.

DIAGNOSIS OF OCULAR ALLERGY

The diagnosis of an allergic ocular disorder depends upon two basic points, the recognition of the probability of a hypersensitive state being concerned in the clinical picture and the proof of an underlying specific hypersensitivity.

The recognition of the probable existence of hypersensitive reactions begins with the history, which often suggests an underlying allergy, the realization that the clinical picture is similar or compatible with an allergic reaction, and the elimination of other manifest causes for the ocular disease—bacterial infection, metabolic disorders, degenerations, and so forth.

The proof of a specific hypersensitivity depends upon the demonstration of an increased cutaneous or ocular reactivity to nonbacterial or bacterial allergens.

The cutaneous reactivity is demonstrated by either the patch or the intracutaneous test. The latter is preferable in as much as it permits exact dosage, and an accurate determination of the degree of reactivity. The intracutaneous test consists in the injection of 0.05 cc. or 0.1 cc. of the various allergens, in varying concentration, in the superficial layers of the skin, raising a small bleb slightly less than the size of a dime. The tests are read at the end of 15 minutes for an immediate anaphylactic reaction, and at the end of 48

hours for the delayed tuberculin-type of reaction.

Increased ocular reactivity is determined by the ophthalmic test. This is, however, neither as simple, conclusive, nor as safe as it first appears, for the local reaction following the direct instillation of a specific allergen in the conjunctival sac may be of such severity that the eye may be permanently damaged. It is therefore doubtful if this diagnostic procedure is justified except in rare instances.

The technique of the ophthalmic test is as follows. An extremely dilute mixture of the allergen is first used (a 1:100 dilution of the dose causing a cutaneous reaction.) One drop is instilled in the conjunctival sac. The patient is instructed to keep his eyes gently closed to facilitate absorption. With the airborne allergens, where the hypersensitivity is of the anaphylactic or pollen type, the reaction is an immediate one, comes on within 15 minutes, and is usually limited to conjunctival erythema.

If the instillation of the weak dilution gives no reaction, the test may be repeated at the end of one-half hour, using a 10 times stronger dilution. Stronger dilutions than a 1:10 dilution of the strength producing a skin reaction should not be used.

If a positive reaction is obtained, manifested by conjunctival congestion, lacrimation, secretion, and so forth, the eye should be immediately and thoroughly washed out with saline and epinephrine hydrochloride should be instilled. With the bacterial allergens where the hypersensitivity is the delayed tuberculin type, any reaction is delayed and comes on only after 24 to 48 hours.

A positive reaction to bacterial antigens may be characterized not only by the erythema and edema, but even by phlyctenules and marginal corneal ulcers. If the test is negative, one is never sure that a sufficient concentration of the bacterial antigen was used, or if absorption took place. Thus negative tests are inconclusive, and positive tests may be disastrous. It is therefore more than

questionable if the direct introduction of bacterial antigens in a suspected hypersensitive conjunctival sac is ever warranted.

When one considers the vast number of protein compounds, air-borne allergens, drug compounds, and bacterial fractions to which an organism may become hypersensitive, the complexity of the diagnostic problem is at once evident. There are, however, certain broad clinical principles on ocular hypersensitivity which may be emphasized.

Primarily there is no evidence that food allergy plays any role in the production of any form of ocular allergy. Patients may be found hypersensitive to wheat, in whom the instillation of the most minute amount of wheat or flour in the conjunctival sac causes the most violent reaction. Such patients do not, however, as a rule develop ocular symptoms after the ingestion of bread, pastry, flour, and so forth. It is reasonably clear that actual contact of the sensitized conjunctiva with the specific allergen is necessary to cause an ocular reaction. This limits the field to the air-borne allergens, the organ-specific tissue extracts, and the bacterial antigens.

I. AIR-BORNE ALLERGENS

The most important air-borne allergens usually incriminated in allergic conjunctivitis are the spores, pollens, inhalants, including house dust and animal dander. In the routine testing of any patient, the tests may be extended to include usual groups of common foods. In actual practice, the various allergens are divided into groups, each containing from 5 to 24 component members. There are some 14 of these groups.

All these various allergens used for testing are standardized on their protein-nitrogen-base content and are diluted to the proper concentration for testing. The spores (Group I) are used in three concentrations: 1:1,000, 1:100, and 1:10. The rare tree pollens (Group II—ash, poplar, and so forth) and the rare grass pollens, (Group III—Bermuda grass, and so forth) are used

1:1,000, 1:100, and 1:10. The epidermals and inhalants (Group IV), of which there are 18 components (black flag, camel hair, cat hair, feathers, cow epidermal, dog hair, stock dust, goat epidermal, horse dander, kapok, orris root, rabbit hair, sheep wool, cotton seed [1:1,000], flaxseed [1:1,000], silk, rayon, tobacco), are used in concentrations 1:100 and 1:10. Groups 5 to 11 and 15 are all foods, vegetables, fruits, grains, dairy products, meats, fish, and common foods. These are all used 1:10 in intracutaneous testing. The nuts (Group 11) are used 1:100 and 1:10. All these allergens, spores, pollens, epidermals, and inhalants, various foods and nuts, are read for the immediate anaphylactic or pollen type of reaction.

II. ORGAN SPECIFIC TISSUE EXTRACTS

A. Uveal pigment. Uveal pigment is not available commercially. It is prepared as follows from fresh beef eyes obtained at a slaughter house. The eyes are scalded and clipped free of adventitious tissue. Under aseptic precautions the cornea is clipped away, the eye opened by a sagittal section, the lens expressed, the retina removed, and the uveal tract dissected out *in toto.*

The uveal tracts of several eyes are then ground in a sterile mortar with salt solution and broken glass until all the pigment has been ground from the tissue. This pigment-containing water is then decanted, precipitated with 50-percent ammonium sulphate, the pigment thrown down and removed by centrifugation. This is then washed six times in sterile distilled water and finally taken up in normal salt solution, 5.0 cc. of salt solution to each uvea. This gives a 0.5-percent pigment concentration. Tricresol (0.5 percent) is then added as a preservative.

The cutaneous sensitivity is determined by injecting 0.1 cc. of the pigment suspension intracutaneously. The site of injection is then read for erythema and induration at the end of 30 minutes and 1, 2, 24, and 48 hours. In a positive reaction there is often a visible

macroscopic cutaneous reaction at the end of one hour and 24 hours. The pigment is so slowly absorbed that this dermal reaction may be inconspicuous.

The diagnosis of a positive reaction is usually made by histologic study of the excised skin. At the end of two weeks the bit of skin containing the ·pigment is excised and sectioned for microscopic study. The microscopic appearance of a positive reaction is striking. The tissue is densely infiltrated with lymphocytes, epithelioid cells, and giant cells, and practically all the pigment is phagocytosed by the epithelioid and giant cells. In a negative reaction, the pigment is inertly distributed throughout the dermis, without cellular reaction or cellular invasion of the tissue.

B. Lens protein. Lens protein for testing and treatment is not available commercially. It is prepared as follows. Beef eyes are obtained from the slaughter house. Under aseptic conditions the lenses are extracted. The lenses are immediately taken up in one-hundredth normal NH_4OH, with 0.5-percent tricresol added, 20 cc. to each lens. These are then shaken 24 hours with broken glass, the gross particles removed by centrifugation and passed through a coarse (B) Berke-feld filter. A specimen of the filtrate is then dehydrated at 104° C. and the total solids are determined. The balance of the filtrate is then adjusted to 2-percent concentration of lens protein and 0.85-percent NaCl by adding distilled water and 10-percent NaCl solution.

The cutaneous sensitivity is determined by the injection of 0.1 cc. of the 2-percent solution intracutaneously. The test is read at 1 hour, at 24, and at 48 hours. Theoretically, the reaction should be an immediate one, but lens protein is such a weak antigen that the reaction is usually of the delayed type. As a control, 0.1 cc. of 0.5-percent tricresol in salt solution is used.

III. BACTERIAL ANTIGENS

When the infinite number of bacteria to which mankind is continually exposed is con-sidered, and the number of antigenically distinct strains which exist for many organisms, it is manifestly impossible to examine for hypersensitivity to all bacteria, or completely to exclude bacterial hypersensitivity in any given case. All that is practical is to examine for hypersensitivity to what appear to be the most important organisms, and when hypersensitivity is found, to determine, when indicated, the specific strain responsible for the sensitivity.

In inflammations of the external eye, where the hypersensitivity is certainly the result of contact with air-borne bacteria, the most important organisms are the staphylococcus, and to a less degree the streptococcus. In uveitis, the hypersensitivity is the result of contact of the uveal tract with organism in the blood stream. In the non-granulomatous disease, the most important organisms are the streptococcus, and to a less extent the gonococcus. In the granulomatous form the most important organisms are the Mycobacterium tuberculosis and Brucella. With these various organisms there are certain basic immunologic and bacterial concepts which should be remembered.

A. Staphylococci. The diagnosis of hypersensitivity to staphylococci or their products is determined by use of the staphylococcus toxin or toxoid. Staphylococcus toxin is prepared by growing a toxin-producing strain of staphyloccus in hormone bouillon for 10 days at 37°C. Tricresol (0.5 percent) is then added, the culture is centrifuged, and the supernatant fluid is filtered through a Berke-feld V filter. The toxoid is prepared by growing the staphylococci on semisolid agar under partial carbon-dioxide tension, and the filtrate is detoxified with formaldehyde.

The toxin and toxoid further differ in that the toxin contains no rabbit erythrocyte hemolysin or dermonecrotizing factor and is not lethal for young rabbits but is highly toxic for older rabbits. The toxoid contains these factors and is moderately toxic for rabbits of any age. Both filtrates produce, in horses, serums which are equally effective

in neutralizing the lethal effects of toxin in rabbits. The toxin is not usually available commercially, while the toxoid is so available. Both have equal therapeutic effects in man.

The cutaneous hypersensitivity is determined by the injection of 0.1 cc. of a 1:100 dilution of the toxin intracutaneously, and by the later injection of a similar amount of a 1:1,000 or 1:10 dilution, depending on whether the first injection gave a positive or a negative result. The reaction is of the delayed tuberculin type, coming on from 24 to 48 hours after the test injection. A reaction of 3 by 3 cm. to the 1:100 dilution is regarded as the usual reaction in a normal individual. Reactions greater than this, or similar reactions to a 1:1,000 dilution are regarded as indicative of hypersensitivity.

Individuals with this hypersensitivity appear peculiarly susceptible to contact with toxin-producing staphylococcus, the mechanism of local infection appearing to be an antigen-antibody reaction. Such hypersensitive individuals may be protected by repeated injections of the staphylococcus toxin (or toxoid), the injections being repeated with stronger dilutions until the individual is nonreactive. Whether this is a desensitization process or an active immunization is not clear—it is probably the former. The toxin prepared from any strong toxin-producing organism gives this protective reaction not only against toxin-producing strains, but also against the nontoxin-producing albus strains and against the pus-producing strains.

B. Streptococci. The situation as concerns the streptococci is far more complex and there is no individual strain or universal toxin which permits a quick and easy manner of determining streptococcus sensitivity. The streptococci are generally divided into the alpha, beta, and gamma types on the basis of their hemolysis. The alpha streptococci produce a greenish discoloration and partial hemolysis on blood agar plates. This group includes the Str. pyogenes, Str. viridans, some four or more other strains of a relative low-grade pathogenicity for man. The

beta produces clear hemolysis on blood agar plates and contains most of the human pathogens. The gamma group gives no hemolysis, and the streptococci of this group are rarely pathogenic for man.

The beta group is subdivided into various subgroups, A, B, C, D, E, F, G, H, and K, on the basis of different antigenic action. Each subgroup has a common polysaccharide, but the individual strains differ in their bacterial body proteins.

The "A" group is by far the most important and contains most of the streptococci pathogenic for man. The various strains in this group differ in acid-soluble proteins known as the "M" and "T" substances. The nature of this "M" and "T" substance determines the individual antigenic action. In the "A" group of the beta streptococci are now 42 known pathogens for man, all antigenically distinct.

The B, D, E, H, and K groups are only rarely pathogenic for man. The "F" group is the minute beta staphylococcus. There are a few pathogens in the "C" group, probably closely related antigenically. There also appear to be a few low-grade pathogens for man in the "G" group, probably related antigenically.

Thus the complexity of demonstrating a specific hypersensitivity to streptococci is apparent. Such a sensitivity must finally be determined by intracutaneous tests with the individual strains. In actual practice the following are the minimum number of test vaccines which should be used: Alpha streptococci, one strain; Beta streptococci—subgroup A, all 42 strains; subgroup C, one strain; subgroup F, one strain; subgroup G, one strain; Gamma streptococci, one strain. If desired, the study may be further extended by the use of additional strains of the Alpha, representatives of the subgroups B, D, E, H, and K of the Betas and by additional pathogens from the Gamma group.

The test vaccines are prepared as follows: Organisms of each strain are grown for 24 hours on trypticase soy broth, are killed.

washed to remove traces of the broth or any exotoxin, taken up in salt solution, a preservative added, and the density of the vaccine standardized to the desired concentration on a spectrophotometer.

In actual practice it has been found that the optimum concentration of a test vaccine for individual strains is a 1:10 dilution of T-50, or approximately T-5. In higher concentrations the protein content is so great that nonspecific reactions may be elicited. The patient is tested intracutaneously with 0.1 cc. of each of the 42 strains of the "A" group and one representative of the B, C, D, F, and G groups. The tests are read at the end of 48 hours.

As a short cut to determine sensitivity to the 42 individual "A" strains, four master mixtures are sometimes used. These master mixtures each contain 10 or 11 individual strains. The concentration is adjusted to a 1:10 dilution of T-50 and the patient tested intracutaneously with each master mixture. The mixture to which the patient gives the strongest reactions is noted, and the patient is then tested out similarly to each of the component members of this master mixture.

The weakness of using such master strains is that the combination of individual strains lowers the concentration of each strain to such a point it may be too low to elicit reactions. If the individual strains are used in higher concentrations to compensate for this dilution, the resulting protein content of the master mixture may be so high that nonspecific reactions result.

In the interpretation of results, it should be remembered that, since exposure and infection with streptococci is more or less frequent in all patients, undue consideration should not be given to weak reactions, and a test vaccine should not be used in too great concentrations.

C. Gonococcus vaccine

The antigenic structure of the gonococci is largely unknown. There are probably two main types with different but probably related antigenic properties. These two strains are supposed to occur respectively in acute infections (Type I) and in chronic infections (Type II). Between these two extremes may be a number of intermediates, containing antigenic fractions common to both main types. Further, there is some evidence that the nucleoproteins of the gonococcus resemble those of other Gram-negative cocci, and the polysaccharide fraction is related to the polysaccharide fraction of Type III pneumococci. Thus the complexity of the problem is evident, and the difficulty of establishing a specific hypersensitivity is likewise apparent.

In routine testing with vaccines prepared from gonococci, if Type I and Type II are available, the patient may be tested with each strain. Probably equally significant results are obtained by the use of any single strain. For diagnostic use the vaccines should be prepared in the concentration which gives the most specific readings. This concentration is usually about T-50. The vaccine is preserved with 0.5 tricresol. The test injections are made in the forearm, 0.1 cc. of vaccine being injected intracutaneously with a proper saline control containing 0.5-percent tricresol. The tests are read in 15 minutes for the immediate anaphylactic type reaction to the polysaccharide or hapten group and at the end of 24 and 48 hours for the delayed tuberculin type reaction to the bacterial body protein.

D. Organisms from a focus of infection

The probable relationship of remote foci of infection to endogenous ocular disease has long been recognized. The mechanism through which a focus of infection produces inflammatory changes in a remote tissue or organ has been a subject of considerable controversy. It is now generally assumed that the probable mechanism is through bacterial hypersensitivity, the remote tissue or organ becoming sensitized to the organisms from the focus of infection, and intoxication resulting from absorption of the soluble bacterial products from the focus.

The only means of demonstrating such a

hypersensitivity is by determining the bacterial flora of the infected focus, selecting such organisms as appear suspicious, and testing the patient's cutaneous sensitivity to these organisms.

Test vaccines should thus be prepared from suspicious organisms cultivated from a focus of infection. Organisms other than streptococci are probably best used in a T-50 concentration, and the streptococci in a 1:10 dilution of the T-50. The test dose is 0.1 cc. intracutaneously with proper controls. Lacking definite information of the antigenic action of such organisms, the tests should be read at the end of 15 minutes for an immediate reaction, and at the end of 48 hours for the delayed reaction.

E. Other organisms

The other common pathogens appear relatively unimportant in the production of a bacterial hypersensitivity of the eye, although their possible role in the production of allergic ocular reactions has not been adequately explored. A specific sensitivity for pneumococci is difficult to determine, since the specificity is determined by the polysaccharide fraction, and to date at least 70 or more antigenically distinct strains have been isolated. The delayed reaction to the protein fraction of the pneumococcus is not type specific.

There has been some circumstantial evidence produced incriminating the coliform bacilli in uveitis. It has been shown that the colon bacteria produce in culture media a toxic substance which has an irritative action on the uveal tract. There is, however, no evidence yet adduced of a hypersensitive state to the coliform organism in patients with uveitis, or the importance of such a hypothetical hypersensitivity.

There is little or no evidence that other bacteria or bacterial products, H. influenzae, and so forth, are concerned with endogenous ocular disease, although it is highly probable that many other heretofore unsuspected strains of bacteria, as well as filterable viruses, may ultimately be incriminated in

both nongranulomatous and granulomatous uveitis.

F. Tuberculin

Cutaneous hypersensitivity to tuberculin may be determined either by old tuberculin or by the Purified Protein Derivative (P.P.D.). The technique of the intracutaneous test (Mantoux) is as follows:

a. Old tuberculin. Three intracutaneous injections of O.T., with one saline control, are made.

Right forearm (upper) Control—0.1 cc. normal saline with preservative
(lower) 0.001 mg. O.T. (0.1 cc. O.T.—1:100,000 dilution)
Left forearm (upper) 0.01 mg. O.T. (0.1 cc. O.T. —1:10,000 dilution)
(lower) 0.1 mg. O.T. (0.1 cc. O.T. —1:1,000 dilution)

If there is no reaction to 0.1 mg. after 48 hours, 0.1 cc. of O.T. (1:100 dilution) is given. This represents an intracutaneous dose of 1.0 mg. If there is no reaction, the patient is considered insensitive to tuberculin. If the patient shows a strong reaction to the test dose of 0.001 mg., the test is repeated with 0.0001 mg. (0.1 cc. of dilution— 1:1,000,000) to determine the limit of extreme hypersensitivity.

b. Purified Protein Derivative. The P.P.D. comes in two vials. Vial No. 1 contains 0.0002 mg. P.P.D. to the cc.; vial No. 2 contains 0.05 mg. P.P.D. to the cc. The intracutaneous dose is 0.1 cc. of these two strengths, the equivalent of 0.004 mg. O.T. and 1.0 mg. O.T. respectively. If the patient reacts to strength No. 1, he is considered highly sensitive, if only to test No. 2, as slightly sensitive, if negative to vial No 2, as insensitive.

In the interpretation of the cutaneous reactivity to tuberculin the following fact must be borne in mind. If the cutaneous sensitivity is high, the ocular sensitivity must likewise be considered as high, since the ocular tissues participate in any generalized hypersensitivity. However, it has been clearly demonstrated experimentally that there can be active tuberculous disease in the eye with high ocular reactivity to P.P.D., while the

cutaneous sensitivity is low. The probable reason for this is that, in the absence of other tuberculous lesions, a tuberculous lesion within the scleral envelope is insufficient to influence the cutaneous reactivity to any appreciable degree. Another possible explanation would be that the increased vascularity in the eye, produced by the local lesion, may be responsible for the increased local reactivity. These two explanations are of academic interest rather than clinical importance.

G. BRUCELLA

The diagnosis of chronic brucellosis can be made only on an evaluation of a number of factors. These are the history, the present symptomatology, the exclusion of other etiologic factors, the presence of certain immunologic tests—the agglutination reaction, the complement fixation reaction to Brucella antigens, the opsonocytophagic index against living Brucella organisms, and the cutaneous reactivity to Brucella bacterial fractions. Table 1 from Huddleson gives a summary of the usual interpretation of these serologic reactions:

chronic brucellosis—nummular keratitis and recurrent uveitis—occur as a rule rather late in the chronic disease, and occur usually in individuals with a relatively high degree of cutaneous sensitivity. These patients appear to do phenomenally well under vaccine treatment which tends to lessen or abolish the sensitivity at the same time it immunizes.

The cutaneous sensitivity in brucellosis is determined by the intracutaneous injection of either brucellin or brucellergin, preferably the latter. Brucellin is the filtrate of a 20-day-old broth culture of one of the Brucella strains, Br. melitensis, Br. abortus, Br. suis, sterilized and preserved. Brucellergin is the protein nucleate fraction from all three strains. Theoretically, and indeed in practice, brucellergin gives more precise and specific reactions than brucellin.

In actual practice, 0.1 cc. of either brucellin or brucellergin is injected in the flexor surface of the forearm, with proper controls. The reaction is a delayed one of the tuberculin type and is read at the end of 24 and 48 hours. Positive reactions are erythema, edema, and induration from 2 to 10 cm. in

TABLE 1

SUMMARY OF USUAL INTERPRETATIONS OF SEROLOGIC REACTIONS TO BRUCELLA ANTIGENS*

Agglutination Test	Allergic Skin Test	Opsonocytophagic Power to Blood	Status Toward Brucella
—	—	Zero to 20 percent of cells, slight	Susceptible
—	+	Zero to 40 percent of cells, marked	Infected?
+	+	Zero to 40 percent of cells, marked	Infected
—	+	60 to 100 percent of cells, marked	Immune
+	+	60 to 100 percent of cells, marked	Immune

* From Huddleson.

The test for cutaneous sensitivity becomes positive relatively late in the disease, and may be present when the agglutination titer has fallen to zero. Once positive, the cutaneous reactivity may persist for years. The relation of sensitivity to the course and type of the lesions has never been worked out in brucellosis to the same extent it has been in tuberculosis. It is noteworthy, however, that the ocular symptoms associated with

size and may often persist for a period up to 5 to 7 days.

TREATMENT OF ALLERGY OF THE EXTERNAL EYE

The cardinal principles of treatment of external allergic disorders of the eye are (1) isolation, (2) specific desensitization, and (3) adjuvant therapy. If the specific allergen responsible for the hypersensitive re-

action is known, the first objective in treatment is isolation of the patient from the offending allergen. If this is impossible, then specific desensitization must be considered. Adjuvant treatment is the use of local palliative measures, washes to remove secretion and promote cleanliness, weak astringent collyria to control the tearing and prevent secondary infection, the use of various antihistamine preparations to give symptomatic relief in the anaphylactic type of reaction, and the use of beta irradiation to clear up the large follicles of vernal catarrh.

1. ISOLATION

The isolation of the patient from the offending allergen may be sufficient to give complete relief and so avoid the tedious and oft-repeated courses of desensitization. Once the specific compound, pollen, animal dust, feathers, cosmetics, or what not, has been identified, the condition is carefully and fully explained to the patient. It is amazing how often a simple readjustment of life may solve the problem.

Thus the patient sensitive to certain pollens takes his vacation during the local season and moves to another environment where the pollen is not present; a patient sensitive to feathers uses a glass floss or hair pillow, gets rid of the pet canary, and eats, sells, or gives away his chickens; the woman hypersensitive to a face powder or certain cosmetics changes her brand to one of the many free of orris root or such substances; the individual sensitive to cat or horse dander shuns cats and horses as he would the plague. These examples may be multiplied endlessly.

The essence of treatment here is accurate diagnosis—the detection of the offending allergen. With all the various pollens, dusts, epidermals, and so forth, it is evident that this is always difficult, and at times may be impossible. Yet the experienced allergist frequently shows the ingenuity of a Sherlock Holmes, and at times it appears almost

miraculous when the answer is produced. It must be remembered, however, that isolation therapy can be applied only to patients hypersensitive to the air-borne and epidermal allergens. Patients hypersensitive to bacterial allergens have no method of avoiding contact with the common pathogens.

2. SPECIFIC DESENSITIZATION

A. Nonbacterial allergens. Specific desensitization is a long and laborious procedure. Some people may be almost impossible to desensitize. Even when successfully accomplished there is a great tendency for the sensitivity to return, and the successfully desensitized patient must be kept under observation, repeatedly tested for a return of the sensitivity, and treatment instituted either annually, or on recurrence of the cutaneous reactions or symptoms.

Desensitization with the pollens, dusts, inhalants, foods, epidermals, and so forth is primarily the problem of the allergist. In view of the somewhat unsatifscatory results of such desensitization therapy in the treatment of external ocular allergy, the ophthalmologist and internist are probably wisest to advise desensitization only when the condition cannot be controlled by isolation and the adjuvant therapy of local washes, collyria, and antihistamine drugs.

If desensitization with the spores, pollens, inhalants, or even the foods is indicated, the general principle is to make up the desensitizing extract in a strength so that the initial dose (0.1 cc.) contains each of the various antigens to which the patient reacted, in a maximum of one hundredth or one thousandth the dose producing a cutaneous reaction.

Thus, for a patient reacting to 0.1 cc. of a 1:1,000 giant ragweed dilution, 1:100 Bermuda grass, and 1:10 orchard grass, the desensitizing treatment extract would contain these allergens in such strength that 0.1 cc. of the treatment vaccine would contain the equivalent contained in 0.1 cc. of a

1:100,000 dilution of giant ragweed, of a 1:10,000 dilution of Bermuda grass, and a 1:1,000 dilution of orchard grass. However, there is often no parallelism between the cutaneous and systemic reactivity of the patient to the allergens, and it is essential that there be no constitutional reaction to either the initial or to subsequent injections. Therefore, in the case of some individuals, the initial dose may be 1:10,000 or occasionally 1:100,000 of the test cutaneous dose.

The initial dose of the mixed allergens is 0.1 cc. The injections are given subcutaneously every four days and increased 0.1 cc. at each dose until a dose of 0.9 cc. is reached. A dilution 10 times the strength of the original preparation is then used, the initial dose again being 0.1 cc. and again is increased to 0.9 cc. when a 10 times stronger dilution is used. This is repeated until a concentration 100 times, and occasionally 1,000 times, the concentration of the original mixture is attained. After a dose of 0.9 cc. of the highest concentration is reached, this dose should be repeated first at weekly intervals, and then at biweekly intervals for an indefinite period, even years. Certainly this maintenance dose should be repeated as long as there is any suggestion of symptoms or activity; otherwise the sensitivity will almost certainly return.

B. Bacterial allergens. The question of desensitization with bacterial extracts and vaccines is quite different from desensitization with air-borne allergens. In bacterial hypersensitivity, isolation from the incriminated bacteria is usually impossible, and the physician has little else to offer the patient except desensitization and some adjuvant therapy. Desensitization in bacterial hypersensitivity should therefore be advised when palliative or adjuvant therapy is insufficient, when the severity of the ocular condition justifies such treatment, and when the promise of success is insufficiently great to make the effort worthwhile.

There are two allergic conditions of the external eye which fulfill these criteria. These are the dry irritative conjunctivitis associated with staphylococcus-toxin hypersensitivity and phlyctenulosis associated with tuberculin hypersensitivity. The use of other bacterial fractions or vaccines in other forms of allergic conjunctivitis or keratoconjunctivitis is of too uncertain outcome to warrant their use unless the disease is of unusual severity and all other possible methods of therapy have been exhausted.

STAPHYLOCOCCUS TOXIN. Desensitization with staphylococcus toxin is accomplished by the repeated intracutaneous injection of the toxin. In patients with an initial reaction not over 8 by 8 cm. to the 1:100 dilution, the 1:100 dilution is the first strength used. If the patient reacts definitely to the 1:1,000 dilution, or gives a greater than 8 by 8 cm. reaction to the 1:100 dilution, a weaker dilution (1:1,000) is used for the initial treatment. A dose of 0.1 cc. of the first dilution is given every four days until the patient no longer gives repeated reactions to this amount. The strength is then increased to the next stronger dilution—1:10 or 1:100 as the case may be, until again the patient no longer reacts to the injection.

Thus, the strength of the toxin is increased and treatment continued until the patient tolerates 0.1 cc. of a 1:10 dilution, or in exceptional cases to 0.1 cc. of the pure toxin without reaction. This is regarded as the final point of desensitization.

A patient may react violently to one injection, and later injections give only a minimal effect. After the point of desensitization is reached, a weekly dosage of 0.1 cc. of the 1:10 dilution should be given at weekly intervals for a period of at least six months to maintain desensitization and prevent the recurrence of the sensitivity which otherwise so often occurs.

PHLYCTENULES WITH TUBERCULIN. The treatment of phlyctenules with tuberculin is identical with the treatment of tuberculous uveitis with the same agent and is discussed below.

3. ADJUVANT THERAPY

A. Local washes and collyria. In allergic

reactions of the external eye there is frequently a good deal of lacrimal secretion and discharge. The object of washes is to cleanse the eye and prevent the matting of the lashes with the dried secretion. This is best accomplished by the use of bland washes, warm physiologic saline, or warmed 2-percent boric-acid solution. The dried crusts along the lids may be removed by gently swabbing the lid margins with a cotton swab moistened in the wash. If the crusts are adherent, they may be readily loosened by moistening the lid margins with a saturated solution of bicarbonate of soda. The secretion and congestion may be partially controlled by the use of an astringent collyrium containing also a small amount of epinephrine hydrochloride.

B. *Antihistamine therapy.* The toxic symptoms of the anaphylactic reaction are quite similar to those caused by histamine. The reaction is therefore usually considered due to the liberation of histamine or a histaminelike substance which acts directly on the fixed cells. The obvious direct therapy would therefore be the use of drugs which would either neutralize or prevent the toxic action of the histamine or histaminelike substance.

In 1937, drugs with such an antihistamine action were isolated in the Pasteur Institute in Paris, but they were too toxic for human use. Later derivatives were prepared which had a diminished toxic action. Since then, pharmacologists in France, Switzerland, and this country have improved and modified these early antihistaminic drugs with the result that there are now available at least eight such preparations—Benadryl, Pyribenzamine, Hydryllin, Histadyl, Thenylen, Theophain, Neo-Antergan, and Antistine. Most of these compounds have the same general chemical structure, the basic radical being either two phenyl rings, or a benzyl, an pyridyl, a thiodiphenyl, or a thiophenyl group.

Experimentally it has been found that these antihistaminic drugs prevent the action of histamine in contracting smooth muscle, inhibit the fatal effect of lethal doses of histamine in guinea pigs, diminish the pressor action of histamine on blood pressure, prevent or decrease the capillary permeability which normally follows the absorption of histamine, reduces the urticarial whealing which follows the intracutaneous injection of histamine, and are more active in preventing anaphylactic shock than are comparable doses of papaverin and epinephrine.

The antihistamines all have a definite anesthetic action; thus Antergan is 3.3., Benadryl 2.5., Antistine 1.5 times as effective as similar strengths of procaine.

Clinical investigations have shown that these antihistamines are of great value in the control of skin irritability, urticaria, the itching which accompanies dermatitis of various types, the skin eruptions which often follow sulfonamides, antibiotics, and organic extracts, and the nasal and ocular symptoms of hay fever and perennial rhinitis. The results in the treatment of bronchial asthma and asthmatic bronchitis have not been too favorable. Hydryllin (a combination of Benadryl and Amnophyllin) and Neo-Antergan have been the most effective in this regard.

There may be various unpleasant side effects with these drugs. Chief of these are drowsiness, dizziness, weakness, tremor, headache, nausea, diarrhea, anorexia, and so forth. It is notable, however, that different drugs react differently in different individuals, both as concerns therapeutic effect, and unpleasant side reactions. It is therefore possible, in any given case, to switch from one preparation to another, seeking the preparation that in the individual patient will give the maximum of therapy combined with the minimum of side effects.

The doses of these various antihistamines vary from 25 to 500 mg. daily for adults, the average effective dose being 50 mg., 3 to 4 times daily. The drugs can be applied topically, in solutions or ointments.

The manner whereby these antihistaminic drugs counteract the action of histamine is not fully understood. Certainly it does not appear to be a direct neutralization or detoxification of histamine, or a prevention of the

antigen-antibody union which leads to the liberation of histamine. Rather, it appears that the antihistaminic drugs are absorbed at the site of action of histamine and so prevent or diminish the absorption or action of histamine on the same cells. In other words, these drugs compete with histamine for position in the target cells, and by occupying these cells block off the absorption and resultant action of histamine.

The effect of the antihistamine drugs in the anaphylactic and pollen types of hypersensitivity has been fairly well established. Little or nothing is, as yet, known of any deterrent action these drugs may exert in allergic reactions resulting from bacterial type of hypersensitivity. It may well be that they may influence profoundly the basic allergic reaction of nongranulomatous uveitis, or depress the inflammatory, caseating reaction in granulomatous uveitis. There is, as yet neither experimental nor clinical evidence of this. There is, however, sufficient evidence to indicate the use of these compounds in external ocular allergy of the anaphylactic type.

In the first two types of allergic conjunctivitis—that is, the sudden, edematous type associated with hay fever, and the edematous type of blepharoconjunctivitis associated with drug allergy—the use of antihistamine drugs is clearly indicated. In the hay-fever type, the usual treatment is 50 mg. of Pyribenzamine, three times daily by mouth. The local symptoms are best controlled by an astringent collyrium containing epinephrine hydrochloride. In the greater number of cases both the nasal and ocular symptoms can be well controlled by such treatment.

In the eczematous blepharoconjunctivitis associated with drug reactions, the itching is often intolerable. In addition to the oral administration of antihistamine drugs, the local use of these compounds may be of value. The one most frequently used is Antistine, which comes prepared in a 0.5-percent solution for ophthalmic use. In a number of cases, this gives effective symptomatic relief when all other collyria fail. How much of the relief is due to the anesthetic action of the drugs is, however, difficult to say.

Since little is known of any effect the antihistamine drugs may exert in bacterial hypersensitivity, there is little indication to use the drugs in the conjunctivitis secondary to staphylococcus-toxin sensitivity. Nevertheless, the use of Antistine locally sometimes appears to control the itching and discomfort. It is quite probable that this action may be due to the anesthetic rather than the antihistamine action of the drug.

In the other manifestations of external ocular allergy—phlyctenules, marginal corneal ulcers, vernal catarrh—there appears to be no indication for the use of antihistamine drugs, although the use of Antistine to control the local itching and discomfort, which so often accompanies vernal catarrh, might be worthy of trial.

C. Beta irradiation in vernal catarrh. Excellent results are obtained in both the palpebral and bulbar forms of the vernal conjunctivitis by irradiation with the beta rays of radium. This form of irradiation is applied preferably with the radon beta applicator described first by Burnam. This is, however, obtainable only in large medical centers where there is a large concentration of radium.

In vernal conjunctivitis almost equally good results can be obtained by the use of the flat radium applicator described by Iliff, containing 50 mg. of radium. This is now available commercially. These applicators give off both the beta and the gamma rays. However, the skin erythema dose (H.E.D.) of the beta rays is 18 gram seconds, while the H.E.D. dose of gamma rays is 8 gram minutes. This differential permits the administration of the full therapeutic dosage of beta, 12 gram seconds, while only a minute amount of gamma is given.

The beta rays penetrate tissue only 2 to 3 mm. They have no effect in the irradiated tissues unless absorbed, their zone of action,

therefore, being limited to a depth of 2 to 3 mm. Their action is essentially an ionization or destructive action in the irradiated tissue. However, some tissues are more sensitive than others, especially rapidly proliferating tissues, embryonic tissue, proliferating capillary endothelium, germinal epithelium and certain neoplasms.

This form of irradiation therapy is especially efficacious against the follicles of vernal catarrh and more so against newly formed fresh follicles than against the older organized pavement-stone vegetations. In vernal catarrh, therefore, it is sometimes wiser to excise the older fibrous follicles before irradiation.

If the Iliff applicator is used, a mechanical holder for the applicator is needed on account of the long duration of treatment. While the applicator holds 50 mg., the effective output is only 30 millicuries. The length of exposure needed to obtain any given number of gram seconds is determined by the following formula:

$$\text{No. sec. exposure} = \frac{\text{No. gm. sec. treatment desired} \times 1,000}{\text{millicuries of radon}}$$

Thus, with an effective output of 30 millicuries, and a desired treatment of 12 gram seconds, 6 minutes and 40 seconds exposure is needed:

$$\frac{12 \times 1,000}{30} = 400 \text{ seconds.}$$

In actual practice, the patient is seated comfortably in a reclining chair with a head rest; the eye is anesthetized with 0.5-percent pontocaine solution; the lid to be treated is everted and held with a clamp or hook. The radium applicator, held in a mechanical holder, is then approached to the lid just short of contact, and a treatment of 6 minutes and 40 seconds given. Two areas in the same lid may be treated consecutively. Treatments are not given oftener than every two weeks to avoid any cumulative effect.

With the Burnam applicator, the treatment is much shorter. This applicator may hold as much as 500 millicuries of radon, all of which is effective. The time of exposure is calculated as above. Thus with 500 millicuries in the bulb, only 24 seconds' direct application would be the full therapeutic dose.

With the Burnam applicator, the follicles, of vernal catarrh are best treated by the "spray" method. In this method the applicator is held by hand about 1 to 3 mm. from the conjunctival surface, and moved slowly back and forth over the area to be treated. Since no one area thus receives the full irradiative effect, the exposure time may be safely increased 50 percent, or a total of 18 gram seconds given over the entire lid. Treatment should not be repeated oftener than every second week. In early cases, where the follicles consist of lymphoid cells, young fibroblasts, and blood vessels, 2 or 3 treatments may be sufficient to obtain an almost complete resolution. In more advanced cases where there is a good deal of fibrosis, more prolonged treatment may be needed.

TREATMENT OF ALLERGY OF THE INTERNAL EYE

The allergic reactions of the internal eye are dependent upon a hypersensitivity of the uveal tract either to one of the organ-specific ocular tissues, or to bacteria or bacterial fractions. The treatment of the allergic phase of the disease by desensitization would be in some instances (nongranulomatous uveitis, endophthalmitis phaco-anaphylactica) a direct attack on what is believed to be the actual cause of the disease, seeking to cure the disease and prevent recurrences by removing the cause.

In other instances (granulomatous uveitis, sympathetic ophthalmia) desensitization therapy would be directed only to the removal of the allergic factor which influences unfavorably the course of the disease. The actual cure of the disease would result

only from treatment with antibiotic or chemotherapeutic agents, or the control and destruction of the specific exciting organisms by the normal body defenses.

DESENSITIZATION WITH ORGAN-SPECIFIC TISSUE EXTRACTS

A. Uveal pigment. Parenteral injections of uveal pigment have been employed in the treatment of sympathetic ophthalmia with the idea of abolishing the phase which appears to set the stage for the outbreak of disease and to determine its histologic picture. The obvious criticism of such treatment is that the pigment in its present preparation is highly insoluble, is very slowly absorbed, and that the pigment sensitivity will probably fade spontaneously before it could be affected by parenteral injections. There is much truth to such criticism. Nevertheless, in the over-all picture, the cases of sympathetic ophthalmia so treated do appear to have done somewhat better than might have otherwise been expected, and to have stood later operations more successfully than would ordinarily have been hoped for.

In actual practice, the 0.5-percent standard suspension of uveal pigment is used. The injections are given at four-day intervals, intramuscularly in the buttocks or deltoid. The first injection is 0.5 cc., the second 1.0 cc., then 1.5 cc., 2.0 cc., 2.5 cc., 3.0 cc., 3.5 cc., and 4.0 cc. The 4-cc. dose is repeated at four-day intervals usually for a period of three months, or until the disease appears burned out.

Pigment therapy is accompanied by a marked increase in the opsonocytophagic index for pigment, and there are evidences of a high degree of phagocytosis of pigment in the diseased eyes (excised iris specimens). This may account for its apparent therapeutic action as well as desensitization.

B. Lens protein. Lens protein is a complex antigen, containing at least two organ-specific globulin fractions and one albumin fraction. It is an excessively weak antigen and, even in heterogenous species of animals, specific

antibodies are produced only with great difficulty. For that reason, in therapy with lens protein, the principle of synergistic action of antigens has been employed. This consists in combining the weak specific antigen with a stronger nonspecific antigen in order to enhance the antigenic action of the weak antigen.

In actual practice in order to desensitize a patient found hypersensitive to lens protein, a mixture of lens protein and staphylococcus toxin is used. To 9.9 cc. of the 2-percent lens protein is added 0.1 cc. of undiluted staphylococcus toxin. This gives a 1:100 concentration of toxin in the lens protein. The initial dose is 0.1 cc. given intracutaneously and this dose is repeated every four days, until the patient no longer shows a reaction.

At this point the patient is tested with 0.1 cc. of the 2-percent lens protein solution. If there is no reaction, desensitization is considered accomplished. If there is a reaction to the lens protein, the patient is then tested with a 1:100 dilution of staphylococcus toxin. If negative to this, he is tested with a 1:10 staphylococcus toxin, and finally to straight toxin, until a dose of toxin is found to which he does react.

A new lens protein-staphylococcus mixture is now made up, containing the reactive dose of toxin, and treatment is continued until the patient no longer shows any cutaneous reaction to an injection of lens protein alone. This is regarded as the point of desensitization. The staphylococcus toxin-lens protein is readily absorbed, and desensitization is usually quickly and readily accomplished within 3 to 6 weeks.

DESENSITIZATION WITH BACTERIAL ANTIGENS

The *principle* of desensitization with bacteria or bacterial extracts is (1) the determination, with the greatest possible exactness, of the specific organism responsible for the hypersensitivity; in the case of bacteria with many antigenically distinct strains, this

involves the further determination of the strains involved; (2) the preparation of the vaccine from the proper strains and also from the proper fractions of the antigenic mosaic; (3) the decision of the proper manner of administering the vaccines, intracutaneous, subcutaneous, intramuscular, or intravenous; (4) the careful observation of the patient during the period of treatment, in order that the dose may be kept below the point of reactivity and increased as the reactivity recedes.

The streptococci and gonococci are the important organisms concerned in nongranulomatous uveitis, and the Mycobacterium tuberculosis and Brucella organisms are the important ones in granulomatous uveitis. In syphilis there is no antigen available to determine hypersensitivity to the Treponema pallidum. There are doubtless many more other exciters of granulomatous and nongranulomatous uveitis, but they are either unknown, or there is no means of testing for hypersensitivity to them.

A. *Streptococcus vaccine.* The indications for the use of a streptococcus vaccine are (1) that the clinical condition be a nongranulomatous uveitis; (2) that there are clinical evidences of systemic nongranulomatous disease (rheumatoid arthritis, a chronic focus of infection, and so forth) or a history of a former nongranulomatous infection with some suggestive time relationship to the ocular disease; (3) that other obvious causes for the ocular disease are eliminated; (4) that the bacterial hypersensitivity demonstrated is specific and is greater than shown by normal controls, and not part of a general reaction to all bacterial antigens.

The route of administration of streptococcus vaccine is of great importance. Experimental work indicates that the subcutaneous administration of killed streptococci often tends to increase the tissue hypersensitivity, while the intravenous administration tends to desensitize.

Wainwright utilized this finding in the vaccine treatment of rheumatoid arthritis,

using the intravenous route for the administration of the streptococcus vaccine. This same principle has been followed in the desensitization for nongranulomatous ocular disease. On the basis of the results so far obtainable, all the "successes" have followed this method of administration, while no improvement has been observed after subcutaneous injections. The intravenous administration therefore appears the method of choice with streptococcus antigens.

Since the hypersensitivity produced by streptococci is dependent upon the acid-soluble proteins of the bacterial body, the vaccine must be prepared from the bacterial bodies themselves. The individual strains are grown in broth for 24 hours, the organisms killed by heat, the bacterial bodies thrown by centrifugation, washed in saline to get rid of any trace of broth or exotoxin, and are finally taken up in salt solution, the concentration adjusted to T-50 on the spectrophotometer, 0.5-percent tricresol added, and this stock suspension cultured for sterility.

The first treatment vaccine should contain the organisms in one-tenth the concentration to which the patient reacted intracutaneously. Since the test vaccine was a 1:10 dilution of the stock T-50 concentration, the "first strength" treatment vaccine should be the pooled 1:100 dilutions of the T-50 stock concentrations of the various strains to which the patient reacted. The second strength treatment vaccine is the pooled 1:10 dilutions of the same T-50 stock concentrations, while the third strength is the straight pooled T-50 stock concentrations of the same strains. After the vaccines are prepared 0.5-percent tricresol is added, and the vaccines are tested for sterility.

The first intravenous dose is 0.1 cc. of the "first strength" vaccine. If there is no general reaction (malaise, fever, leukocytosis, and so forth) the dose is repeated at four-day intervals, and increased 0.1 cc. at each injection until 0.9 cc. is reached. The second strength is then similarly administered. This is con-

tinued in a similar manner until the patient receives 0.9 cc. without reaction. The third strength vaccine is now given and the dose then repeated weekly as a maintenance dose.

After the early injections, the patient should be carefully observed, his temperature followed for 24 hours, and a leukocyte count done four hours after the injection. If the patient shows a reaction to the initial dose of 0.1 cc. of the first vaccine preparation, the preparation is then diluted 10 times, and 0.1 cc. *again similarly administered*. Thus there is determined an original dose below the patient's individual point of reactivity. This is then accepted as the proper starting dose, and the dosage thereafter is increased as outlined above. In the event of a general reaction, or focal reaction in the eye being observed during the course of desensitization, the dose is dropped to one-tenth or one one-hundredth the amount given before the general or focal reaction, and again increased from this point.

The question of how long such treatment should be continued is an interesting one. Since this form of therapy has been used in selected cases in the Wilmer Institute of The Johns Hopkins Hospital, several cases have been encountered which showed the same general picture. Prior to the administration of the streptococcus vaccine the patients had had repeated violent attacks of nongranulomatous uveitis. During vaccine therapy they were free from attacks. Within 3 to 6 months after stopping treatment, the attacks recurred, and the sensitivity to the specific streptococci returned. Further treatment was again followed by freedom from attacks. In actual practice, after the point of apparent desensitization has been reached, it would seem wise to continue the treatment at weekly intervals.

B. *Gonococcus vaccine.* The indications for the use of a gonococcus vaccine are that the patient have a recurrent nongranulomatous iritis, which from the history and associated findings appears to be of gonococcal origin, that he also shows a cutaneous hypersensitivity to gonococci, and that other methods of treatment have been inefficacious in controlling the inflammation or curtailing attacks.

The best route of administration, subcutaneous or intravenous, is unknown. In view of this uncertainty, the wisest course is to adopt the simplest method and administer the vaccine subcutaneously.

The vaccine for treatment should be prepared from the type to which the patient showed the greatest reaction. Commercial stock vaccines may be used if the patient shows an equal sensitivity to them. The original concentration of a prepared vaccine should be one tenth of that to which he showed a cutaneous reactivity. The original dose is 0.1 cc. The injection should be given every third or fourth day, and increased in the usual manner until a dose of 0.5 cc. of a T-500 concentration is reached. A small group of such cases treated in this manner have shown a favorable course. This is all that can be said.

C. *Other organisms.* If it is decided to use a vaccine prepared from an organism isolated from a focus of infection in the patient, the vaccine should be prepared as used or described for gonococcus vaccine.

D. *Tuberculin treatment.* Treatment with tuberculin is essentially desensitization therapy. Old tuberculin or one of its many variants is used. Denys' Bouillon Filtrate (D.B.F.), a glycerinated 1:10 dilution of O.T. has certain advantages. Bacillen emulsion is to be avoided on account of the irregularity of dosage that occurs in higher dilution.

For treatment, the D.B.F. is prepared in nine different strengths—No. 1 represents the undilated D.B.F.; No. 2, a 1:10 dilution; No. 3, a 1:100 dilution; No. 4, a 1:1,000 dilution; and so on to No. 9, which is a 1:100,000,000 dilution of the D.B.F., or 0.000,001 mg. to the cc. Thus, 0.1 cc. of the various dilutions represents the following dosages:

Dilution	Dosage
No. 1—straight D.B.F.	0.1 cc. = 100 mg.
No. 2—1:10	0.1 cc. = 10 mg.
No. 3—1:100	0.1 cc. = 1 mg.
No. 4—1:1,000	0.1 cc. = 0.1 mg.
No. 5—1:10,000	0.1 cc. = 0.01 mg.
No. 6—1:100,000	0.1 cc. = 0.001 mg.
No. 7—1:1,000,000	0.1 cc. = 0.0001 mg.
No. 8—1:10,000,000	0.1 cc. = 0.00001 mg.
No. 9—1:100,000,000	0.1 cc. = 0.000001 mg.

In actual practice, the initial dose is usually 0.1 cc. of No. 8. In the extremely sensitive, it is wiser to start with 0.1 cc. of No. 9, or occasionally with a No. 10 dilution. Injections of dilutions 9, 8, 7, 6, and 5 are given twice weekly or at four-day intervals. The initial dose each dilution is 0.1 cc. Subsequent doses are 0.2 cc., 0.3 cc., 0.4 cc., 0.6 cc., and 0.8 cc. When 0.8 cc. of a dilution is reached, the next higher dose is 0.1 cc. of the next higher concentration.

When 0.8 cc. of No. 4 dilution is reached, further injections are given at weekly intervals. The injections numbers 4, 3, and 2 are 0.1 cc., 0.2 cc., 0.3, 0.4 cc., 0.5 cc., 0.6 cc., 0.7 cc., 0.8 cc., 0.9 cc. When a dosage of 0.5 cc. of No. 2 or 50 mg. is reached, the dose is not increased further. This dosage should, however, be repeated at weekly intervals for a minimum period of two years as a maintenance dose to prevent the recurrence of the hypersensitivity which, without maintenance of treatment, is so prone to occur.

During tuberculin treatment the patient should be carefully watched both for local reactions at the site of the injection and focal reactions in the eye. In the case of a local reaction (erythema, induration) of the site of the injection, the dose should be dropped three levels, and increased again when no local reaction is observed. If there is a focal reaction—that is, a lighting up of the inflammatory process in the eye—the dose is dropped to one tenth of that which produced the focal reaction (the dose of the next weakest dilution), is repeated at this level, and is only increased when the focal reaction has subsided.

It should be emphasized that there is no such thing as an absolute dose of tuberculin for any one individual. The essential point of desensitization therapy with tuberculin is to keep the dose beneath the patient's point of reactivity, and to increase the dosage only as the point of reactivity recedes.

D. Brucella vaccine. The three known strains, Br. meletensis, Br. suis, and Br. abortus are certainly all closely related antigenically, all containing varying amounts of identical antigens. They are thus so closely related antigenically that a single vaccine can be used for treatment.

Various preparations have been suggested, the best known being the Brucellin of Huddleson and oxidized vaccine of Foshay.

Brucellin is the mixed clear filtrate of 20-day-old cultures of the known strains. It is administered intracutaneously with the idea of evoking general systemic allergic reactions, and it is considered that 3 to 4 such reactions are necessary to produce any therapeutic effect.

The usual procedure is first to test the patient with an intracutaneous dose of 0.1 cc. of Brucellin. If he does not show a systemic reaction to the dose in four hours, the first treatment dose of 0.5 cc. is given. If the patient does show a systemic reaction to 0.1 cc. this is held as the treatment dose as long as the patient reacts. After the reaction dose is determined, this is repeated at three-day intervals until the patient has had three or more systemic reactions.

Thereafter, the dose is spaced to 15-day intervals and so continued for six months, together with any other supportive treatment (antibiotics, sulfa compounds, and so forth) desired. Advocates of this treatment claim about 25 percent of the chronic cases are benefited. This would appear to be a high figure, and it is somewhat doubtful if the low incidence of improvement warrants the severe systemic reactions entailed.

Various other vaccines, bacterial extracts, and suspensions have been prepared for the

treatment of chronic brucellosis. In the effort to produce a vaccine with a maximal reduction of toxicity and a minimal loss of antigenicity, Foshay has prepared an oxidized Brucella vaccine.

This vaccine is prepared by growing a smooth abortus strain of established antigenicity on solid media or a fortified tryptose broth. The organisms are harvested, killed with formaldehyde, the turbidity adjusted to about T-1,000 in the spectrophotometer, and the organisms then oxidized by taking them up in 30-percent aqueous sodium nitrite, 5 ml. to each 3 ml. of packed bacterial sediment together with 5 ml. of 30-percent acetic acid; the mixture is stored in centrifuge tubes, carefully marked for original volume, and the organisms are thus oxidized 4 to 5 hours at room temperature. Acids and salts are then removed by repeated washings and centrifugation and the oxidized bacteria finally taken up to the original volume in 0.5-percent phenolized saline.

In treatment, four strengths of the vaccine are prepared: T-1, T-5, T-50, and T-500. The initial dose is 0.1 cc. of T-1. The patient is watched carefully for any evidence of systemic reactions. If none are observed, the doses are repeated every second day, and increased 0.1 cc. at each injection until a dose of 0.5 cc. is reached. The concentration of the vaccine is then increased to T-5, and 0.1 cc. is given. This is likewise increased 0.1 cc. at each dose until a dose of 0.9 cc. is reached. The concentration is then increased to T-50, the initial dose is again 0.1 cc., and

it is increased as before until a dose of 0.9 cc. is again reached.

If there have been no reactions, the concentration is increased to T-500 and 0.1 cc. again given. This is increased in like manner until a dose of 0.5 cc. is reached. This is continued twice weekly for two months when the blood should be examined for the opsono-cytophagic index.

In the treatment of patients with chronic ocular brucellosis, the vaccine is always administered with the idea of keeping the dose below the patient's point of reactivity and avoiding all local, focal, or systemic reactions. If there is any systemic or focal reaction at any level, the dose is immediately reduced to one-tenth the amount causing the reaction, and again cautiously given as usual. The treatment is continued until the opsono-cytophagic index shows marked phagocytosis in at least 90 percent of the cells. This development of a high opsonic index is almost invariably accompanied by a diminution in the cutaneous sensitivity.

It is interesting that frequently the patients volunteer the information of improvement in their general health and sense of well being while under treatment. It is not clear whether the local therapeutic effect in the eyes is due to the immunity acquired or produced by the vaccine treatment, or is the result of tissue desensitization. It is interesting, however, that the ocular symptoms have, as a rule, occurred in patients with high degree of cutaneous hypersensitivity.

The Johns Hopkins Hospital(5).

THE OPHTHALMOSCOPIC EVALUATION OF OPTIC ATROPHY*

ALFRED KANT, M.D.

Watertown, New York

A survey of the available literature on the diagnosis of optic atrophy brings forth the familiar triad of symptoms—pallor of the disc, reduced visual acuity, and defects in the visual field. Although, in many cases, these signs permit us to diagnose optic atrophy with a considerable amount of assurance, there remain a number of cases in which they are either not available to us, as in the case of children or others unable to coöperate, or are wholly untrustworthy, as in some cases of retinitis pigmentosa.

In some of these uncertain cases, in spite of all the classical signs and symptoms including the "peculiar waxy atrophy of the disc," subsequent pathologic study has revealed no evidence of atrophy in the nerve even after the use of the myelin-sheath stain.

Most ophthalmologists will admit that the present diagnostic criteria for optic atrophy are inadequate in many cases, with the result that we are frequently forced to play a delaying game, not through any lack of training or thoroughness on our part, but simply because no purely objective method exists for the diagnosis of optic atrophy. It is the purpose of this paper to present a possible method.

Since testing visual acuity and taking visual fields are, in large measure, subjective procedures, we can immediately discount their value. There remains, then, the ophthalmoscopic appearance of the disc. Walsh states that pallor of the discs alone is not evidence of optic atrophy. Adler has summarized the opinions of numerous observers in the following statement, "pallor of the disc may be due to one or all of the following

factors: low hemoglobin content of the blood, diminution in the number of capillaries on the disc, overgrowth of glial fibers and, finally, actual loss of the nerve fibers."

Of these factors, the number of capillaries on the disc facilitate ready and precise ophthalmoscopic evaluation. There are many scattered references throughout the literature pertaining to a loss of capillarity on the disc in optic atrophy but it remained for Kestenbaum, in 1946, to quantitate these small vessels and to point out their possible utility in the diagnosis of primary optic atrophy by what he calls the Kestenbaum capillary number test. To acquaint those not too familiar with this test the following portion of his book is quoted in its entirety:

"In order to set a numerical value on the degree of atrophy, the vessels which pass over the margin of the disc may be counted. One starts at the twelve o'clock point and counts all the vessels crossing the margin, counting separately the arteries, the veins and the small vessels. 'Small vessels' mean the vessels which cannot be recognized as arteries or veins. The number of vessels passing over the margin in normal eyes is fairly constant. Without dilatation of the pupil, usually 9 large vessels (4 or 5 veins and 4 or 5 arteries) and about 10 small vessels can be seen.

"Of course there are many exceptions in normal eyes. Sometimes the arteries and veins branch repeatedly on the disk, so that more than 9 large vessels pass over the disk's edge. In disks with irregular or inverse distribution of the vessels, the number test is also unreliable. In the large majority of cases, however, the arrangement of the vessels is regular enough to permit the use of this test.

"In primary optic atrophy, the number of arteries and veins remain unchanged, but the number of small vessels is diminished to 7, 6 or even less, down to only 3, so that an approximate numerical measure of the degree of pallor is possible. This test may be of value in the observation of the development of the disease." (See Diagram 1.)

This paper does not claim any originality but simply tests the validity of Kestenbaum's conclusions and seeks to extend their usefulness to apply to all cases of optic atrophy from whatever cause.

PROCEDURE

An attempt was made to study all cases of optic atrophy appearing at the out-patient department of the Massachusetts Eye and Ear Infirmary, as well as the house cases on the wards of the Massachusetts General
Diagram 1 (Kant). This drawing of the disc shows the "small vessels." Only those vessels which cannot be recognized as arteries or veins are counted.

Hospital for a period of nine months. Only those cases affording a clear view of the disc were utilized.

The small vessels on the disc were counted according to the method elaborated by Kestenbaum. To make the method as simple and practical as possible, an ordinary electric ophthalmoscope was used. The number of vessels counted was recorded and then refraction and fields were done under comparable conditions. A number of normal eyes were similarly studied and recorded.

The patients varied in age from the 1st to the 6th decade. Of the 65 patients examined, 20 were normal and 45 showed atrophy of some type, affording a total of 125 eyes of which 49 were normal and 76 atrophic.

Etiologic study of the atrophic cases showed:

Primary atrophy, cause unknown	7
Neurosyphilis	3
Nasopharyngeal carcinoma	1
Acromegaly	1
Glioma of chiasm	1
Rolandic meningioma	1
Suprasellar cyst	1
Orbital tumor (meningioma)	1
Retrobulbar neuritis, cause unknown	1
Multiple sclerosis	3
Toxic amblyopia	2
Optic neuritis	5
Vascular occlusion	3
Chorioretinitic disease	2
Fuchs's atrophy	1
Birth injury	1
Auto accident	3
Combined systemic disease	1
Glaucoma	7

Columns for visual acuity ranging from nil vision to 20/15 were laid out and the number of small vessels counted in each case was recorded under the appropriate visual acuity found. The tabulated results were averaged giving a mean number of small vessels under each visual acuity.

Similarly, columns representing the number of small vessels from 0 to 14 were laid out. The visual fields were analyzed by means of a polar planimeter for preserved area of field expressed in square centimeters. The results thus found were tabulated under the appropriate column of the number of vessels in each case. The totals were then averaged for each column. For this study, based upon a number of determinations, an approximately full field constituted between 19 to 22 square centimeters.

It was assumed that the number of small vessels on the disc reflected the overall functional integrity of the optic nerve. Practically, in order to evaluate the nerve, we usually consider two things: namely, the central vision, as shown by the visual acuity, and the peripheral vision, as shown by the area of preserved field.

If our assumption is correct—that the number of small vessels on the disc expresses the degree of functional integrity of the nerve or, conversely, indicates the de-

gree of total atrophy present—then the larger the visual field the greater should be the number of small vessels.

Similarly, the higher the visual acuity the greater should be the number of small vessels, provided decreases in visual acuity were part of an overall atrophy and not due to a selective atrophy involving the papillomacular bundle which could cause a drastic reduction in central vision without causing a commensurate loss in peripheral field.

Graph 1 shows the correlation between the number of small vessels and the area of preserved field expressed in square centimeters. The black dots represent the actual values found in the individual cases and the solid black line represents the mean value of area of field. It can readily be seen that a surprisingly direct relationship exists between these two factors.

Graph 2 shows the mean value of ·the number of small vessels counted plotted as a curve against visual acuity. The black dots represent actual values as found and the solid black line indicates the mean value of

FIGS. 5 TO 8 (KANT). THESE KODACHROMES, AS WELL AS THOSE IN FIGURES 1 TO 4, ARE NOT SUFFICIENTLY CRITICAL TO SHOW THE SMALL VESSELS, IN MOST INSTANCES. SINGLE EYES ARE SHOWN IN ORDER TO ILLUSTRATE THE SCOPE OF APPLICATION OF THE NUMBER TEST
Chart 5. These field studies are for a woman, aged 40 years, for (above) 3/330 white and (below) 1/1,000 and 10/1,000 white. Vision in each eye was 20/30+. The left eye showed six small vessels and the area of the visual field was 9.5 sq. cm. The right eye showed seven small vessels and a visual field area of 10.5 sq. cm.
Chart 6. The visual acuity in the left eye of this patient, a man, aged 49 years, was hand movements temporally. The *number of small vessels* present was three.
Chart 7. Visual field studies for the left eye of a man, aged 23 years, for (above) 5/330 white and (below) 10/1,000 white. Visual acuity in this eye was counting fingers at two feet; six small vessels were counted. Area of field, 18 sq. cm.
Chart 8. The left eye of this man, aged 56 years, had 20/20 vision, and the number of small vessels was eight. (Above) Field for 3/330 white. (Below) Field for 1/1,000, 3/1,000, and 10/1,000 white. The normal right eye of this patient showed 14 small vessels. Area of field L.E., 5.8 sq. cm.

Charts 5 to 8 (Kant). The visual fields are numbered to correspond with the numbers of the Kodachromes they illustrate.

these findings. The numbers under the acuity listings represent the number of cases observed under that acuity.

It can be seen that there is a surprising correlation between the number of small vessels and the visual acuity, especially between the range of 20/200 and 20/15, where an almost linear function exists. Between
Graph 3 (Kant). Correlation of visual acuity, extent of visual field, and number of small vessels. The abscissa represents the visual acuity. The solid line of the ordinate shows the area of field; the dotted line, the number of small vessels.

20/200 and nil vision the curve is less regular.

There are several possible explanations for this segment of the curve:

1. There is the subjective element of error in counting which, however, does not seem too important in view of the fact that the remaining portion of the curve is based on the determinations of the same observer.

2. Only relatively few determinations in this range of the curve were available and it is possible that, if a greater number of cases had been studied, this section might have conformed more closely to the general curve.

3. If the fibers subserving central vision were damaged to a greater extent than the peripheral ones, the visual acuity would then be expected to be low, with preservation of a relatively large field. Since the number of small vessels expresses the degree of overall atrophy, there would be present a relatively greater number of vessels than would be expected for that acuity. In effect, this is exactly what happened in these cases in this portion of the curve as is shown in Graph 3.

Graph 3, in addition, shows that there is no reliable relationship between the visual acuity and the amount of field preserved except when the atrophy is general and overall.

In those cases, and there were quite a few, in which the number of small vessels found was at variance with the amount of visual acuity, which was either inordinately high or low for reasons already mentioned, the area of preserved field closely approximated the amount expected, the data in Graphs 1 and 2 being used for mean values. These points can be illustrated by reporting a few cases.

CASE REPORTS

Case 5. A man, aged 68 years, had chronic simple glaucoma of both eyes, with marked cupping and atrophy in the left eye and slight in the right eye.

	O.D.	O.S.
No. small vessels	8	6
Visual acuity		
actual	20/30	Fingers at 5 inches
expected	20/30	20/50+
Visual field		
actual	14.8 sq.cm.	13.6 sq.cm.
expected	15.8 sq.cm.	13.6 sq.cm.

Here the right eye shows an excellent agreement between the actual and expected values both as to acuity and area of field. The left eye shows an inordinate decrease in acuity compared to the number of small vessels on the disc. In this instance, apparently, the papillomacular fibers had been severely damaged with resultant poor acuity. The remaining overall, functional integrity of the nerve is shown, however, by the

preservation of exactly that amount of field expected for a nerve with this capillary index. In this case both the ophthalmoscopic appearance of the disc and the markedly reduced visual acuity would have suggested a greater degree of total atrophy.

Case 17. A woman, aged 60 years, had chronic simple glaucoma of both eyes, more advanced in the left eye.

	O.D.	O.S.
No. small vessels	7	2
Visual acuity		
actual	20/40	20/100
expected	20/40	Light perception
Visual field		
actual	18.0 sq.cm.	1.0 sq.cm.
expected	13.4 sq.cm	2.0 sq.cm.

Here again there is a good correlation in the right eye as regards acuity and fairly good as regards field. However, in the left eye there is considerable disparity between the actual and expected acuities. In this case, apparently, the macular fibers were relatively spared. The visual fields both actual and estimated agree very closely.

From these findings one is led to the conclusion that the number of small vessels on the disc quantitatively measures the degree of functional integrity of the optic nerve or, in other words, can be used as an indicator of the degree of overall atrophy present.

It may be of interest to consider the findings in an unquestioned case of retinitis pigmentosa which had all the classical signs and symptoms including the peculiar waxy pallor of the disc so characteristic of the disease.

Case 1. A woman, aged 26 years, had a diagnosed case of retinitis pigmentosa.

	O.U.
No. small vessels	13
Visual acuity	
actual	20/200
expected	20/15
Visual field	
actual	4° fixation (0.5 sq.cm.)
expected	21+ sq.cm.

CONCLUSION

Either the capillary index is no measure of optic atrophy in this case, or there is no optic atrophy present.

In this connection it is interesting to note that Verhoeff, in 1931, reported a case of retinitis pigmentosa that had been blind for 20 years in which the ganglion cells were well preserved and abundant and even the myelin-sheath stain failed to show any evidence of atrophy in the nerve. By citing this case, it is not meant to imply that atrophy does not occur sometimes in this condition. However, the striking disparity in this one case between the obvious waxy pallor and the capillary index of the disc was of sufficient interest to warrant mention.

COMMENT

The number of small vessels is not difficult to count. However, as some of these vessels are quite minute, a little practice will improve one's recognition of them and increase the accuracy and reproducibility of the count. Separate observers, on the first trial, have agreed to within 1 to 2 vessels on the same eye.

Care must be exercised to count only those vessels which cannot be recognized as being either arterial or venous. A darkened room is to be preferred. When the accommodation is active, cycloplegia facilitates the counting considerably.

A clean, well-focused ophthalmoscope with good illumination is essential. In my experience, red-free light was not superior to ordinary light in the final count although it did make the small vessels more striking in appearance.

Noteworthy in this series were two cases of marked physiologic pallor of the disc which had been previously diagnosed as atrophy by several members of the staff. These cases, subjected to the capillary number test, fell well within the range of normal, which impression was subsequently confirmed by refraction and quantitative perimetric studies on the Goldmann perimeter.

One case of partial vascular occlusion failed to show an appropriate correspondence between the number of small vessels and acuity and fields. As far as could be determined, it did not have any anomalous vascularization of the disc.

Although the number of cases in this study is admittedly small, the results from the Kestenbaum capillary number test in optic atrophy are sufficiently suggestive to warrant further study and consideration. The capillary test can serve as an interesting adjunct and check on the more usual diagnostic tests, when these are available. In those cases in which visual acuity and field studies are impossible, for whatever reason, the capillary number test may afford the only clue to diagnosis.

SUMMARY

In this study, 125 eyes—49 normal and 76 atrophic—were examined. The number of small vessels on the disc was counted according to the Kestenbaum capillary number test. The visual acuity and area of field were determined in each case. These findings were correlated with the number of small vessels and expressed in graph form.

CONCLUSION

The capillary number test as elaborated by Kestenbaum is a valuable adjunct in the diagnosis of optic atrophy from whatever cause and would seem to be a reliable measure of the degree of atrophy present.

EPITHELIAL TUMORS OF THE CILIARY BODY*

Joseph A. C. Wadsworth, M.D.
New York

Introduction

The significance of certain tumors of the ciliary body has been a controversial subject, since Treacher Collins,[1] in 1891, first reported a case of primary tumor of the ciliary body in a woman, aged 63 years. Following Collins's report, Alt[2,3] and Fuchs[4] wrote rather extensively on the subject. Both of these authors endeavored to classify the various growths and discussed their etiology. Fuchs,[4] in 1908, reported eight cases and classified the tumors according to the microscopic morphology.

The description of some of these tumors led Collins[5] to postulate the glandular nature of the ciliary epithelium, a point which is still adhered to by some observers (Leber,[6] Rados,[7] Seidel,[8] Carrére,[9] and others).

General discussion

Most writers have agreed on the main factors influencing the classification of these primary tumors of the ciliary body. The main factors generally considered are: (1) Cell morphology, (2) age of the patient, (3) extent of growth, and (4) significant past history.

Fuchs[4] laid the greatest stress on the first factor in his classification; however, he was influenced by the second and fourth factors also. The extent of growth was of comparatively little importance in his classification.

Nordmann[10] gave less attention to the past history and gave a greater significance to the extent of growth.

For the purpose of this discussion Nordmann's classification is acceptable and will be used:

I. Benign tumors
    A—Hyperplasia
    B—Benign epithelioma (adenoma)

II. Malignant tumors
    A—Embryonic type (dictyoma)
    B—Adult type

Collins[1] described his first case as an adenoma and numerous subsequent reports of different authors have used the same term for the small tumors originating from the ciliary epithelium. Fuchs[4] in his thorough treatise on the subject coined the term "dictyoma" (net-tumor) to describe those tumors of the ciliary body whose cells are embryonic in type.

Those tumors which show evidence that the cells are embryonic in type may even form what appears to be an embryonic retina. Often these are indistinguishable from retinoblastoma (neuro-epithelioma).

For the most part these tumors have been found only in children; whereas, the more differentiated cells are seen in adults around the age of 50 years. The large majority of the latter type have no clinical signs or symptoms referable to the presence of an intraocular new growth. These tumors have been found in globes enucleated for various reasons and have had no demonstrable influence on the condition of the ocular illness.

A comparatively large percentage of the patients who reveal these small epithelial tumors of the ciliary body have a past history of ocular inflammation so that this point has been seriously considered as an etiologic factor (Fuchs,[4] Alt,[11,12] Duke-Elder,[13] and others). However, the percentage incidence of inflammation is not sufficiently high in these cases to render it significant statistically.

Following Nordmann's classification will facilitate the discussion of the various primary epithelial tumors of the ciliary body.

I. Benign tumors

A. Hyperplasia

The simple hyperplasia of the ciliary epithelium may form cell masses resembling a small neoplasm. There may be a pigmented or nonpigmented epithelial mass originating from the ciliary epithelium. Such growths usually extend toward the interior of the globe and they do not penetrate into the ciliary processes or ciliary body proper. The arrangement of the cells is usually quite irregular without evidence of any typical

tion of the nonpigmented epithelium but the pigment epithelium may participate in the process as well.

For the most part this hyperplasia involves the region of the ciliary processes but frequently long strands and fingerlike formations may extend from the pars plana (Salzmann).

Case 1

History. A 40-year-old man was struck in the eye during childhood. Following the injury the eye gradually became blind. On occasions the eye became injected with moderate discomfort. Symptoms
Fig. 1 (Wadsworth). High-power magnification of section in Case 1 at region of ciliary body. (A) Marked hyperplasia of ciliary epithelium extending axialward (B).

organization of the elements. The cells are large with oval nuclei and seem to be simply piled on one another in the form of sheets with occasional folds or scallops.

Eyes with such lesions have a long history of "eye trauma," either as a long-standing recurrent iritis or inflammation following injury. Such changes in the epithelium are frequently seen also in senile eyes. The hyperplasia in some cases may be so general as to push the iris forward and embarrass an already narrowed filtration angle. Generally, the senile hyperplasia is a prolifera-

were not sufficiently severe to consult an ophthalmologist until three weeks prior to admission. At the time he was first seen the eye was painful and exhibited marked ciliary injection, the cornea was steamy, and the tension markedly elevated. Clearing of the cornea revealed a cataractous lens with iris bombé. The eye was excised with a clinical diagnosis of absolute glaucoma, secondary to detachment of the retina, and cataract.

Macroscopic. The globe was of normal size. The anterior chamber was very shallow and there was a complete detachment of the retina.

Microscopic. There is edema of the cornea with a loss of epithelium. A wide peripheral anterior synechia is present completely occluding the filtration angle. A well-formed glass membrane resembling Descemet's extends from the posterior

surface of the cornea onto the anterior surface of the iris. The iris substance shows perivascular round-cell infiltration and some plasma cells. Occlusion and seclusion of the pupil is present and a large fibrous plaque exists on the anterior surface of the cataractous lens. The lens contains calcium.

The muscle of the ciliary body shows some hyaline degeneration, and the ciliary processes have lost, somewhat, there delicate structure and contain a hyalin material. Round-cell infiltration is prominent around the larger vessels. The epithelium of the ciliary body is thickened and reduplicated in places. Numerous vacuoles resembling fat deposits are seen in the nonpigmented layer.

In the region of the pars plana (fig. 1) there is a breaking up of the pigment epithelium with some proliferation. Extending axially from this area is a proliferation of the nonpigmented epithelium. These cells extend centrally and are arranged in sheets and irregular scallops. The central portion of the mass resembles a fibrous core but contains no vessels. In some areas of the proliferation there is marked vacuolation with a pink homogeneous material beneath. No necrosis or active inflammatory response can be found in the tumor.

Enmeshed amongst the zonules are small spheres of large epithelial cells arranged in various forms. These masses have no visible connection with the ciliary body, but are probably cross sections of similar processes described above.

The cells comprising the mass are large, typical epithelial cells with small oval nuclei and moderately clear cytoplasm. No abnormal or immature cells are seen.

This is a good example of hyperplasia of the ciliary epithelium.

B. BENIGN EPITHELIOMA

This tumor may be described as a well-circumscribed cell mass composed of non-pigmented cells encapsulated by a single layer of pigmented cells. These tumors are found by chance in the globes enucleated for various reasons but the high percentage is found among those eyes excised for glaucoma and neoplasms. Nearly all of these growths are seen in patients over 50 or 60 years of age. They are rarely over one millimeter in diameter and have apparently caused no symptoms because of their presence.

The tumor proper is composed of large oval epithelial-like cells with oval nuclei. The outer layer is arranged perpendicularly to the surface and the nucleus is near the base of the cells. This arrangement gives a sort of

palisade along the outer portion of the tumor. The central portion is composed of cellular strands of 1 to 2 layers thick arranged perpendicularly to their long axis. Occasionally one sees an arrangement resembling rosettes. In such a case the polarity of the cells is still present with the nuclei in the outer circumference. The central portion is usually empty or may contain a pink-staining material. The central region of the tumor may show atrophic cells and vacuolization but no necrosis. No vessels or connective tissue are seen in these small tumors.

No true capsule is formed, but the outer surface is lined with pigment epithelium and not infrequently these cells become atrophic and lose their pigment—even disappear in places. On the inner surface of the ciliary body there is always a break in the pigment epithelium and this is the origin of the tumor. This could be called the hilum.

Case 2

History. A 67-year-old married woman with a basal-cell carcinoma of the lid had been given a large but unknown quantity of X ray and radium during the month prior to admission. The eye became injected and painful and an enucleation was done at the time of extensive resection of the lids.

Macroscopic. The globe is of normal size and grossly shows no abnormalities.

Microscopic. There is a complete loss of the corneal epithelium. Bowman's membrane is intact except peripherally where there is marked invasion of new vessels and connective tissue completely replacing the membrane. There is also an invasion of vessels into the stroma peripherally. Descemet's membrane and the endothelial layer appear normal.

The iris shows some hyalinization of the sphincter muscle and generalized atrophy of the stroma with a cellular condensation on the anterior surface. These cells appear to be a proliferation of the endothelial cells.

There is proliferation of the nonpigmented epithelial cells which fill up the recesses of the processes of the ciliary body (fig. 2-a). Embedded in the ciliary processes is a circumscribed collection of epithelial cells arranged in irregular scallops along the outer margin. The central area (fig. 2-b) is made up of irregular strands and numerous spaces of pink-staining material. No necrosis is seen. The tumor contains no true capsule but is surrounded by a layer of pigment epithelium. Numerous areas of atrophy can be seen. A well-marked hilum is demonstrated.

The lens shows proliferation of the anterior
Fig. 2-a (Wadsworth). Benign epithelioma in region of ciliary body demonstrating the proliferation of the nonpigmented epithelium. The tumor shows the typical scalloped arrangement of the epithelial cells (B). (A) points to the hilum.

subcapsular epithelium with some vacuolization and liquefaction of the anterior cortical region. Deep in the cortical region are islands of embedded subcapsular epithelial cells. In the posterior subcapsular region there is also liquefaction, all of which is typical of cataractous changes secondary to radiation (Reese[14]).

There is marked thickening of the lamina vitrea
Fig. 2-b (Wadsworth). High-power view of area indicated by square in Figure 2-a, showing the hilum, scalloped arrangement of epithelial cells and the lack of connective-tissue stroma.

and these areas contain fine granules of calcium.

This is a good example of a benign epithelioma of the ciliary body.

II. MALIGNANT TUMORS

A. EMBRYONIC TYPE OR DICTYOMA

This has been called primary carcinoma by Lagrange.[15] It is seen in children between the ages of 1 and 8 years but there are two cases in the literature, one aged 16 years (Böck[16]) and one aged 28 years (Soudakoff[17]), with ciliary body tumors which meet

Fig. 3-a (Wadsworth). Photomicrograph of section from the A. B. Reese collection, showing the malignant nature of the embryonic-type tumor of ciliary body. The tumor has eroded the sclera at the limbus and has extended outside the globe (A). This case was reported by Böck.[16]

all the criteria for their classification as an embryonic type of tumor.

In these tumors there is a questionable inflammatory background. Most observers do not consider inflammation statistically important in these cases.

The structure (fig. 3-a) consists of cell membranes of cylindric epithelial cells with

nuclei arranged in two or more rows with their axis vertically. There may be solid masses of cells like those seen in retinoblastoma and there may be rosettes (fig. 3-b). Invasive nature is a prominent feature and the iris, cornea, and sclera are often affected. The free surface may possess a limiting membrane not unlike the internal limiting membrane of the retina. Tubes, bands, and cavities are common to all tumors of this type.

Fig. 3-b (Wadsworth). A high-power view taken at the area indicated by square in Figure 3-a, showing the cell formation. Rosettes (A) and cords (B).

Case 3

The slide was graciously loaned to me by Dr. A. B. Reese. A 16-year-old girl, who had been blind for about eight months, showed clinically a staphyloma at the limbus nasally. The globe was stony hard. Vision was light perception. This case was described by Böck.[16]

B. ADULT TYPE OF MALIGNANT TUMOR

This is seen in patients between the ages of 10 and 73 years, but the great majority of these patients are seen between the ages of 50 and 65. Of the cases reported in the literature some stress was laid on those cases which gave a history of inflammation or injury. Fuchs[4] reported a case of old septic endophthalmitis with bone formation which demonstrated an epithelioma of the ciliary body that infiltrated into and even destroyed the bone. The majority of the cases have a history of gradual decrease of vision with occasional episodes of pain. Clinically, lenticular opacities associated with appearance of a mass in the region of the angle are the most common signs. Less than half of the cases reported showed elevation of tension.

Case 4

Dr. J. H. Dunnington was kind enough to permit me to include this case in my series.

History. The patient, a 63-year-old man, gave a history of failing vision of the left eye for 3 to 4 years. There was no history of injury or inflammation; no history of pain or tenderness in either eye.

Examination. Vision was: L.E., 20/70; R.E., 20/20. Tension was normal in both eyes. The cornea of the left eye was clear with normal luster. The anterior chamber was of normal depth except in the region between the 12:30- and 3-o'clock positions where the iris was pushed forward. At about the 2-o'clock position the iris was cystic and there was a small pigmented area, 1.5 by 2 mm., in the peripheral region of the iris near the angle. Upon dilatation of the pupil, the lens showed cataractous changes which were dense in the upper nasal region. The lens was displaced backward.

Gonioscopically (fig. 4), the iris was pushed forward obliterating the angle in the region of the 12- and 3-o'clock positions. On the anterior surface of the iris was a heavily pigmented area beginning in about the middle of the iris and extending toward the angle. The pupillary region appeared atrophic in the upper nasal sector. Behind the iris a round heavily pigmented mass was pushing the iris forward and at the same time was displacing the lens backward where the tumor was in contact with the lens and the cataractous changes were most dense.

Because of the clinical appearance of the tumor, a diagnosis of malignant melanoma of the ciliary body and iris was made and the left eye was removed.

Macroscopic. On section of the globe an oval-shaped tumor of the ciliary body and base of the iris was seen. The tumor was covered with heavy pigment and was in contact with the lens pushing it backward. The mass measured about 3 by 3 mm.

Microscopic (fig. 4-a). A section of the cornea has been removed for keratoplasty. The remainder of the cornea is normal except for a region near the limbus which is the area of the tumor.

In the upper temporal aspect of the ciliary body

Fig. 4 (Wadsworth). The gonioscopic picture shown by Case 4. The tumor is pushing the iris forward and is in contact with the lens posteriorly. The dark area on the anterior surface of the iris is the extension of the tumor.

there is an oval-shaped tumor mass measuring 3.5 by 4 mm. The neoplasm appears to have arisen from the base of the ciliary body and pushed the ciliary processes backward. The tumor is fairly well circumscribed except near the base of the iris where it has destroyed this tissue and infiltrated into the corneal lamellae, meshwork of the iris, and ciliary body proper. Sheets of cells are seen on the anterior surface of the iris. These cells are large epithelial-like cells arranged in a sheet.

The cells of the tumor proper are for the most part nonpigmented epithelial-like cells arranged in sheets, cords, and folds that resemble tubules. There are many areas which show atrophy and cystic degeneration but no necrosis. The many spaces are filled with a pink-staining material. In these areas the cells are flattened and lose their distinct cell outline.

Where the tumor (fig. 4-b) involves the base of the iris the cells become heavily pigmented. Otherwise pigment is sparse. However, where the growth has engulfed the ciliary processes the collections of pigment remain.

At the angle (fig. 4-c) the iris is completely replaced by tumor and these cells fill the angle as well as the meshwork. The adjacent tissue shows local infiltration but the cells are well differentiated and maintain their polarity, all of which is indicative of a relatively slow-growing tumor.

Very few new vessels are seen in the tumor and true connective-tissue stroma is lacking.

The infiltrative characteristic, as well as the destruction of the iris, suggests that this tumor has malignant potentialities—certainly it is locally malignant.

This tumor is a primary epithelioma of the adult type.

Butler and others[18] also described a tumor not unlike the above case which also showed extension onto the anterior surface of the iris. This was seen clinically as a tongue-shaped area of pigmentation on the anterior surface extending toward the pupillary area. The case reported by Keyes and Moore[19] showed a replacement of the iris in the region of the tumor and the lens capsule was ruptured and tumor tissue had infiltrated into the cortex of the lens.

Fig. 4-a (Wadsworth). A low-power photomicrograph, showing the tumor in the region of the ciliary body.
Fig. 4-b (Wadsworth). A high-power view of a section of the tumor taken from the area indicated by the square in Figure 4-a. It shows infiltration of tumor into stroma of cornea. The cells are arranged in cords and bands with very little connective-tissue stroma. Cells at the base of the iris contain pigment.

One of our patients (Case 5)* was younger than usual, being in his 20th year. Clinical signs of cataract were the first symptoms noted two years previously and showed persistent progress. Next, the iris became atrophic and pushed forward into the anterior chamber. At this time dilatation of the pupil revealed the tumor to be in the region of the ciliary body. The tumor (fig. 5) in this case eroded the capsule of the lens by its axial growth. This direction of growth is responsible for the early symptoms before more destruction of the iris and ciliary body could take place. The histology is identical with the previously discussed case.

DISCUSSION

A true picture of the reported cases is a difficult problem because so few of the

benign tumors have been recorded as an individual case. For the most part, the
Fig. 4-c (Wadsworth). Section at a different level, showing the infiltration of the iris and the implant of tumor on the iris (A) as was seen clinically in Figure 4.

* See page 1497 for description.
Fig. 5 (Wadsworth). Case 5. This shows the tumor encroaching on the lens with subsequent cataractous changes. At (A) the capsule of the lens is ruptured.

smaller tumors were described in passing while the eye was being reported for some unrelated condition.

Fifty-eight cases of epithelial tumors have been reported in the literature[1-5, 10-12, 17-21] and of these a high percentage have scanty descriptions with insufficient information to classify them accurately. However, Figure 6 is a simple table which gives some comparative data of the three types of tumors. As can be seen, the benign epithelioma (adenoma) was found in older patients but none was seen clinically. The apparently high percentage of inflammation is interesting but not significant since 41 percent of 1,938 consecutive eyes enucleated at the Institute of Ophthalmology, New York, either showed pathologic evidence, or gave a definite history, of inflammation. These large adult epitheliomas showed a very low incidence of inflammation. The statistics on the embryonic type is of no significance since more than half of the cases gave no history at all.

Levy-Wolfe[21] subdivided these small tumors into three classes according to the location in the ciliary body (fig. 7):

TYPE & NUMBER	AV. AGE	AV. SIZE	PREVIOUS INFLAMMATION
CASES FROM LITERATURE			
BENIGN 32	58	1.0 mm.	YES - 66% NO - 12 " ?-22%
MALIGNANT 10 (adult)	34	3.8 mm.	YES - 16% NO - 84 "
MALIGNANT 16 (embryonic)	11	2 mm. to full globe	NO - 43% ? - 57 "
THE AUTHOR'S CASES			
BENIGN EPITHELIOMA 10	61	0.48 mm.	YES - 20% NO - 80 "
MALIGNANT EPITHELIOMA 9 (adult)	56	2.8 mm.	NO - 43% ? - 57 "

Fig. 6 (Wadsworth). Comparative data of the types of epithelial tumors reported in the literature and herein reported.

Class I. The pedunculated type on the surface of the ciliary body.

Class II. Countersunk in the substance of the process.

Class III. Completely embedded in the process.
Fig. 7 (Wadsworth). A diagrammatic representation of the three classes of ciliary-body tumors as described by Levy-Wolfe.

Such a classification is an unnatural one and is of no real importance. By study of serial sections a single tumor may fit into more than one classification depending on the level at which the tumor was sectioned.

The first section of our Case 6* (fig. 8-a) shows a small tumor in the substance of the ciliary body which would place the growth

Fig. 8-a (Wadsworth). Case 6. This shows the tumor in the substance of the ciliary body and classified, according to Levy-Wolfe, as Class 3.

* See page 1497 for description.

Fig. 8-b (Wadsworth). The same tumor as shown in Figure 8-a but at a different level and classified, according to Levy-Wolfe, as Class 1.

in Class III. Another section (fig. 8-b) of the same tumor shows an entirely different location and this time the tumor would be placed in Class I.

These so-called benign adenomas may continue to grow and extend beyond the confines of the pigment epithelium and into the substance of the ciliary body proper (fig. 9). As the cells extend into the stroma of the

Fig. 9 (Wadsworth). A small epithelial tumor with cells extending outside the confines of the pigment capsule indicating early malignancy with local extension.

ciliary body, they become larger and more nearly spherical in shape, and they often form small acini. This growth certainly indicates local malignancy.

The formation of these tumors has aroused

Preceded by the invagination of the non-pigmented cells, there is an invagination of the pigmented cells forming a potential cavity into which the nonpigmented cells can grow. If the nonpigmented cells do not keep
Fig. 10 (Wadsworth). (A) A diagrammatic picture of a normal ciliary body. (B) The beginning formation of a small epithelial tumor, showing the invagination of the pigment epithelium with a proliferation of the nonpigmented epithelium. (C) A further development of the tumor in (B), showing the palisade arrangement of the epithelial cells along the pigmented portion. (D) The progress of the tumor is shown by the rupture of the pigmented layer and the infiltration of the cells into the substance of the ciliary body proper.

sufficient interest to cause some writers to speculate on the manner in which they develop. It is generally agreed that proliferation of the nonpigmented epithelium is the most active process; however, the pigmented epithelium must play a part. All cases of the so-called benign epitheliomas or adenomas are partially, if not completely, surrounded by the pigmented epithelium. There is always a small break in the pigment epithelium through which the nonpigmented cells grow (fig. 10-a, b, c, d).

pace with the pigmented cells, a cyst may be formed.

From the above process there is a hilum formed and a pedunculated tumor in reverse is the result.

In conclusion I believe it is obvious that these small so-called benign epitheliomas may grow and show malignant characteristics as manifested by the destruction of tissue and infiltration. Extension outside the globe in the adult tumors has not been seen because alarming symptoms arise early in the

disease and the eyes are usually removed.

The embryonic type is far more malignant and has the characteristics of a retinoblastoma.

REPORT OF CASES*

In the pathology department of the Institute of Ophthalmology there are 20 cases of primary epithelial tumors of the ciliary body (fig. 6).

Case 5

Graciously loaned to me by Dr. W. T. Boland.

History. A 20-year-old white man had worn glasses for the past 12 years. His refraction has been checked at regular intervals. Two years ago the lens of the left eye showed some cataractous changes but one year later he passed an army test for vision but, after another year, the vision of the left eye was 20/100, not improvable.

The lens was markedly cataractous with the greatest opacification in the nasal half. The iris was pushed anteriorly against the posterior surface of the cornea on the nasal side by a growth in the region of the ciliary body. The iris in this region was atrophic.

Upon dilatation of the pupil, the edge of the growth could be seen. It had a brownish color and was in contact with the lens. The angle was completely blocked nasally. The fundus was poorly seen because of the lens changes. The tension was normal. No family history of malignancy could be elicited.

The macroscopic picture showed a well-circumscribed, brownish mass in the ciliary body nasally. The iris was pushed forward in this region and the lens was pushed temporally and posteriorly. The remainder of the eye was normal.

The microscopic picture reveals the cornea to be normal. Nasally the iris is pushed forward by a round cellular mass originating from the base of the ciliary body. There is a wide posterior synechia over this area with some proliferation of pigment cells of the iris. The tumor mass extends axialward to compress and displace the lens temporally. The nasal portion of the lens is cataractous with some calcium deposits in the lens cortex. The tumor has eroded the capsule of the lens.

The tumor is made up of large epithelial cells with pink cytoplasm and round or oval, lightly stained nuclei. The cells are arranged in cords, bands, and occasional acini. Some areas show atrophic changes characterized by pale, indistinct cell outlines with some cystic degeneration. No necrosis is present. Very few vessels are seen and there is no evidence of inflammation. The greater part of the tumor is surrounded by pigment epi-

---

* Cases 1 to 4 have already been described.

thelial cells, but none of the tumor contains pigment and there is very little supporting tissue seen.

The remainder of the ciliary body is normal except for some edema in the region of the tumor. The retina and choroid are normal and there is no evidence of inflammation.

Histologically this tumor is identical with those small "benign" epitheliomas, but this has grown large enough to have been seen clinically and has injured the lens.

Case 6

The patient was a 50-year-old man who had a marked exophthalmos and optic atrophy.

Microscopic. The corneal epithelium shows keratinization. The remainder of the cornea, anterior chamber, and iris are normal. Embedded in the ciliary processes is a well-circumscribed epithelial tumor measuring 0.3 mm. in diameter. One section shows the tumor completely surrounded by the ciliary process; whereas, at another level the small tumor is on the surface of the ciliary body. The basal cells of the tumor are perpendicular to the surface and the center of the tumor is made up of strands of cells arranged perpendicular to the long axis of the strand. Usually these strands are two cells thick. Between these bands is a pink-staining material. This is an epithelioma of the adult type.

Case 7

The eye was removed from a middle-aged man because of a basal-cell carcinoma of the lid with extension to the conjunctiva.

Microscopic. Polymorphonuclear infiltration into the cornea with some extension of the basal-cell epithelioma at the limbus.

Near the base of the ciliary body there is a small, nonpigmented tumor measuring 0.3 by 0.4 mm. The pigment epithelium is invaginated and its continuity is broken at one place where the tumor cells are spreading outside the confines of the pigment epithelium.

The tumor is made up of the large epithelial cells arranged perpendicular to the *outer surface.* The cells in the center of the tumor are roughly ovoid and are arranged in bands and primitive acini. These central cells have variable shaped nuclei; some are round and others are spindle-shaped. No visible supporting tissue can be seen. The cells that have pushed their way outside the confines of the pigment epithelium into the substance of the ciliary body are more nearly round. This is an example of an epithelioma with local extension.

Case 8

History. A 26-year-old man with an intraocular foreign body of six weeks' duration showed chronic inflammation and finally hypopyon. The eye was enucleated for fear of sympathetic ophthalmia.

Microscopic. There is an oblique wound through

the cornea nasally, 2 mm. from the limbus. Some sections show incarceration of the iris in the wound and an increase in vascularization of the cornea between the wound and the limbus. Many polymorphonuclear cells also infiltrate the iris stroma. There is a large laceration of the anterior and posterior capsule of the lens. There is, also, an abscess of the vitreous with a sprinkling of polymorphonuclear leukocytes along the surface of the internal limiting membrane. The choroid and retina are also affected with the same inflammatory process.

In the ciliary body near the base is an aggregation of nonpigmented epithelial cells. The pigment epithelium has become invaginated and forms what appears to be a capsule. Other sections show this to be incomplete and the cells are infiltrating (pushing) out into the substance of the ciliary body. The cells are arranged roughly in rosettes and sheets. The oval nuclei are perpendicular to the outer circumference of the rosettes and located peripherally. The center of these rosettes is filled with a pink-staining material. Several small capillaries are seen and a few scattered connective-tissue cells too. When the pigment epithelium is lacking and the nonpigmented cells are extending from the main mass, the cells are more nearly round and arranged in solid groups. This is an example of epithelioma of the adult type.

Case 9

History. A 77-year-old man had acute glaucoma following the use of atropine five years ago. An iridectomy was done shortly after. There was no history of inflammation.

Microscopic. The epithelium is separated from the cornea by a sheet of connective tissue in the area of the operative incision. Descemet's membrane is incarcerated in the stroma of the cornea. There is a wide peripheral anterior synechia. The ciliary body shows many of its processes to be calcified.

In the region of the base of the ciliary body there is a collection of epithelial cells arranged in whorls and bands with a central structureless pink-staining material. The pigment epithelium is indented and partially surrounds the nonpigmented cells. There is no invasion of tissue. This is a benign epithelioma.

Case 10

History. An 81-year-old man with absolute glaucoma had had a paracentesis two days prior to enucleation. No history of inflammation was present.

Microscopic. The iris is trophic and a membrane of fibrous tissue extends over the anterior surface of the iris.

In the atrophic ciliary body is a small area of proliferation of nonpigmented epithelial cells curled into sheets. The outer portion is lined with the typical large epithelial cell. Several small capillaries can be seen inside the tumor and vacuolization is a

prominent feature. There is no infiltration. Impression—benign epithelioma.

Case 11

Long-standing chronic noncongestive glaucoma. Pneumococcal corneal ulcer two weeks prior to enucleation.

Microscopic. Loss of corneal epithelium with polymorphonuclear infiltration through the layers of the stroma with loss of substance. Anterior chamber contains large numbers of polymorphonuclear cells with posterior corneal abscess. Iris is infiltrated with polymorphonuclear leukocytes.

Near the region of the pars plana of the ciliary body there is a break in the pigment epithelium with invagination of the nonpigmented epithelium. These cells are arranged in sheets and acini. At one area the pigment epithelium is missing and the nonpigmented epithelium is growing free in the stroma of the ciliary body. This is evidence of local malignancy of a small epithelioma.

Case 12

History. A 79-year-old woman had a growth on the inner surface of the lid, bulbar conjunctiva, and cornea of the left eye. The corneal growth proved to be an epithelioma of Bowen's type.

Microscopic. There is a projection of the nonpigmented epithelium into the substance of the ciliary body. Between the cells is a pink-staining material. There is a break in the pigment epithelium.

The nonpigmented epithelial cells are arranged in sheets and cords with some scalloped arrangement. No newly formed vessels are seen. This is a benign epithelioma.

Case 13

History. Age unknown. Failing vision for one year. Irregularity of the pupil and a small elevated area of iris in the pupillary area at the 1-o'clock position. The elevated area increased in size under observation. Tension = 100 mm. Hg (Schiøtz). Enucleation was done because of a blind, painful eye with a suspected tumor of the iris.

Microscopic. The section has badly faded but cytology is possible. The cornea is normal except for irregularity of epithelium. The filtration angle is open but the meshwork of the angle shows thickening and sclerosis of the trabeculas. The iris is thickened in the pupillary region by an infiltration of a spindle-cell tumor which appears to arise from the sphincter. The lens is normal.

In the region of the sims in the ciliary body there is a well-circumscribed tumor, measuring 0.5 by 0.5 mm., composed of large epithelial cells originating from the nonpigmented epithelial cells of the ciliary body. The tumor is partially surrounded by the pigmented cells except in the region of the hilum.

The outer portion of the tumor is lined with the nonpigmented cells arranged perpendicular to the

surface and with nuclei toward the base of the cell. The central area contains many empty spaces. These areas are made up by the numerous bands and sheets of cells forming a coarse network. These bands are two-cells thick arranged perpendicular to the long axis of the bands. No newly formed vessels or connective tissue are seen in the substance of the tumor. No evidence of inflammation is present. Impression—(1) Leiomyoma of iris; (2) benign epithelioma of the ciliary body.

Case 14

History. A 56-year-old woman had had failing vision in the right eye for over one year. There was no pain or inflammation. Physical examination revealed a large detachment of the retina with questionable transillumination. The pigmentation was extremely heavy throughout the eye.

Microscopic. The entire uveal tract is thicker than usual, especially on the temporal side where it is four times its normal thickness and the chromatophores are engorged with pigment.

In the ciliary body near the base is an aggregation of nonpigmented epithelial cells almost completely surrounded by pigment epithelial cells. The outer cells are arranged perpendicularly to the outer margin of the tumor and the nuclei are near the base. The inner portion is made up of irregular bands or sheets and poorly formed acini. No connective tissue or newly formed vessels can be seen in the tumor.

Diagnosis. Melanosis oculi and benign epithelioma of the ciliary body.

Case 15

A 35-year-old woman who had had failing vision for one month presented no history of injury or inflammation.

Microscopic. Arising in the choroid in the lower temporal portion of the globe is a pigmented tumor which has pushed the ciliary body axialward and forward. The tumor has produced a detachment of the retina and the tumor of the choroid is made up of cords of epithelial cells containing pigment. The outermost part of the tumor contains pigment but the central portion shows areas of necrosis and hemorrhage.

In the region of the sims there is a small, circumscribed, nonpigmented tumor composed of epithelial cells resembling those of the nonpigmented cells of the ciliary body. The tumor is almost completely surrounded by pigmented epithelial cells. There is a single layer of nonpigmented cells along the outer surface arranged perpendicularly to the surface and their nuclei are near the base of the cells. The tumor proper is made up of irregular acini and scallops with many spaces. These spaces are filled with a pink-staining, homogeneous material.

Diagnosis. Malignant melanoma of the choroid and benign epithelioma of the ciliary body.

Case 16

No history is available.

Microscopic. The cornea shows some irregularity of the epithelium with some evidence of cornification. In the central region of the cornea Descemet's membrane is irregular and absent in places. In these areas there is proliferation of the endothelium with deposits of pink-staining material. The anterior chamber is of normal depth.

Along the anterior surface of the iris is a sheet of large epithelial cells varying from one cell to 6 or 7 cells thick. These cells are arranged in solid sheets and some have the appearance of columnar cells. One mitotic figure is seen. Numerous empty spaces are seen in the tumor. These cells also course along the inner surface of the cornea and across the angle and completely occlude it. There is occlusion and seclusion of the pupil by extension of the tumor.

In the region of the base of the ciliary body and the base of the iris there is an accumulation of large, nonpigmented epithelial cells arranged in sheets and poorly formed acini. These cells extend into the ciliary body proper and onto the surface of the iris.

The remainder of the eye is not remarkable. There is no evidence of inflammation.

Diagnosis. Malignant epithelioma of the ciliary body; glaucoma, secondary to tumor.

Case 17

No history is available.

Microscopic. The eye has been subjected to a severe inflammation which has subsided with the result of extensive bone formation which almost completely fills the interior of the globe. Many of the internal structures are not identifiable.

In the region of the ciliary body is a mass of epithelial cells arranged in irregular tubes and folds. The outermost group of these cells contain pigment. The central portion of the tumor is atrophic and the cells are arranged in cords and bands. The adjacent bone has been eroded by the neoplasm.

Diagnosis. Malignant epithelioma of the ciliary body in an old phthisical eye.

Case 18

No history is available.

Microscopic. In the region of the ciliary body and the iris there is an epithelial growth extending into the anterior chamber and destroying the immediate portion of the iris. The tumor cells have infiltrated into the inner layers of the sclera near the scleral spur.

The original portion of the tumor is typical in its formation but, as the tumor has extended and gained momentum, numerous bands and membranes can be seen associated with many empty spaces. In the region of the iris the cells contain pigment but elsewhere the tumor is free of pigment.

Diagnosis. Malignant epithelioma of the ciliary body.

Case 19

History. A 77-year-old woman with senile cataracts had had no history of inflammation. The tension was normal. An intracapsular extraction of the left eye was followed by detachment of the choroid and softening of the eye. Six weeks later the tension rose to 70 mm. Hg (Schiøtz) and treatment failed to relieve the pain. The eye was subsequently removed.

Microscopic. The cornea showed some vascularization of the deep layers of the stroma and in the anterior chamber and on the anterior surface of the iris there are two large cystlike areas made up of epithelial cells. The retina is detached and there is marked thickening of the lamina vitrea and proliferation of the pigment epithelium of the retina.

In the ciliary body there is an accumulation of nonpigmented epithelial cells which forms a well-circumscribed tumor. The mass is surrounded by pigmented epithelial cells. Cellular arrangement is typical with the benign epithelioma.

Diagnosis. Epithelization of the anterior chamber; glaucoma secondary to epithelization of the anterior chamber; benign epithelioma of the ciliary body.

Case 20

History. The patient was struck in the right eye 22 years previously and there was no light perception following the injury. The eye was blind and shortly before enucleation the eye became injected and painful.

Microscopic. The globe is somewhat deformed. The cornea is irregular in thickness and irregularity of Descemet's membrane is seen at one place. There is sclerosis of the pectinate ligament with occlusion of Schlemm's canal. Atrophy of the iris with edema is well marked and edema extends to the ciliary body.

In one of the ciliary processes near the base is a cellular collection of nonpigmented epithelial cells which is partially encapsulated by pigment epithelial cells. Near the base of the tumor the pigmented epithelial cells are not present and a well-formed hilum can be seen. The cells in the outer portion of the tumor are perpendicular to their base and the nuclei are in the outer portion of the cells. The central portion is made up of irregularly arranged cells but there is a tendency to form acini, the lumina of which contain a pink material.

Diagnosis. Benign epithelioma of the ciliary body.

73 East 71st Street (21).

OPHTHALMIC MINIATURE

Egyptian Ophthalmology

In Egyptian writing, the corneal ulcer was symbolized by the crocodile. The Greeks, who did not know the crocodile from first-hand experience, used the crab as a symbol for a painful disease, and corneal ulcer was cancer to them.

RETROBULBAR ALCOHOL INJECTIONS*

RELIEF OF OCULAR PAIN IN EYES WITH AND WITHOUT VISION

A. EDWARD MAUMENEE, M.D.

San Francisco, California

The treatment of prolonged severe ocular pain is one of the most trying problems in ophthalmology. Frequently partially seeing eyes and blind eyes which are not disfiguring or otherwise dangerous are removed because the patients can no longer tolerate the pain caused by them. In many instances these patients can be relieved of pain for several months or longer by the use of retrobulbar alcohol injections. If during this interval the cause of the pain is alleviated, the eyes might be saved and in some instances useful vision retained. Retrobulbar alcohol injections should, therefore, have a very definite place in the armamentarium of ophthalmic therapy.

For many years encouraging reports on this procedure have appeared in the German and French literature but its use has not been so well accepted in this country. In the few reports which have appeared in the English literature the possibility of complications in the form of extraocular palsies and injury to the optic nerve have been stressed. It is the purpose of this communication to report the use of retrobulbar alcohol injections for ocular pain in 41 blind eyes and 15 eyes with partial vision. These injections were given by members of the staff of the Wilmer Institute of Ophthalmology between the years of 1942 and 1948.

Grüter[1a] published the first report on the use of retrobulbar alcohol injections in 1918. In 1943[1b] he reviewed the literature and summarized his experiences of 25 years with this therapy. He advocated the use of 1 to 3 cc. of 80- to 90-percent ethyl alcohol without previous injection of novocain in blind painful eyes as an alternative for enucleation. The transient complications of chemosis of the conjunctiva, slight proptosis of the globe, and extraocular palsies which follow alcohol injections were described in some detail. Only a few patients who received an injection of 3 cc. of 80- to 90-percent alcohol developed a permanent paralysis of the ocular muscles. In Grüter's 25 years of experience with this therapy he observed only one case of neuroparalytic keratitis after an injection of 3 cc. of 70-percent alcohol. The complications of herpetic keratitis and corneal ulcer, which not infrequently follow injections of the Gasserian ganglion, were not encountered in his cases.

In 1930 Weekers[2a] reported the use of 40-percent alcohol injections for the relief of pain in patients with seeing eyes who had corneal ulcers, keratitis, uveitis, and primary congestive glaucoma. He injected 1 cc. of novocain, removed the syringe from the needle and, after five minutes, injected 1 cc. of 40-percent alcohol. He again reported the use of this procedure in 1939[2b] and 1941[2c] and stated that he had occasionally observed a temporary paralysis of one or more of the extraocular muscles but had not observed any permanent complications. Damage to the optic nerve was not noted from this procedure. In some cases of primary glaucoma, the ocular tension was reduced for a few days to a week following the injection. He suggested that this therapy be used to lower the ocular tension so that an interval operation might be performed. Weekers thought that alcohol injections had a curative effect in some cases of anterior uveitis and interstitial keratitis.

Magitot[3] has also advocated retrobulbar injections of 1 cc. of 40- to 50-percent alcohol for painful inflammations of the anterior segment of the eye (such as interstitial keratitis, gonococcal iritis, and phlyctenular ker-

atitis) and for acute congestive glaucoma. He stated that he had never seen a permanent extraocular palsy or injury of the optic nerve from this procedure.

There are only a few references to the use of retrobulbar injections of alcohol in the English literature. Fejer[4] in 1932 reported its use in five cases. Gifford[5] in his book on ocular therapeutics mentioned its value for the relief of pain. Hartman[6] in 1942 referred to the work of Grüter, Weekers, and Magitot. Goulden[7] in 1943 reported that he had found 1 cc. injections of 40- to 60-percent alcohol to be of value in cases of interstitial keratitis, uveitis, and subacute glaucoma, but he did not record how many times he had used this procedure. In the discussion of Goulden's communication, Goldsmith mentioned that he had observed a sterile abscess following the use of an 80-percent alcohol injection in one patient. This complication must be extremely rare for it is not mentioned in the reports of Grüter, Weekers, or Magitot.

The only instance of injury to optic nerve recorded in the literature is the report of Cordes[8] in 1929. In this patient, the optic nerve was injected when an attempt was made to inject the sphenopalatine ganglion. The patient saw a sudden flash of light during the injection, and suffered a permanent total loss of vision. He also developed paralyses of the extraocular muscles and ptosis. The optic nerve became atrophic but the motor function of the muscles returned.

METHOD OF INJECTION AND REACTION

The technique for retrobulbar alcohol injections in the series of patients reported here has been similar to that described by Grüter, Weekers, and Magitot. The patient is requested to look up and nasally and a 3.5-cm., 22-gauge needle is inserted into the lateral third of the lower lid just above the rim of the orbit. The needle is then passed through Tenon's capsule between the external and inferior rectus muscles into the muscle cone. An effort is made to keep the needle as close to the back of the globe as possible. The plunger of the syringe is withdrawn slightly to be sure the needle has not entered a blood vessel. One cc. of 2-percent novocain is injected into the muscle cone. The syringe is removed leaving the needle in place. After 3 to 5 minutes, the corneal sensitivity and extraocular muscles are tested to be sure the needle is in the proper position. A syringe containing 1 cc. of ethyl alcohol is attached to the needle and the solution injected into the orbit. The patients frequently complain of a sharp pain in the orbit or a dull occipital headache for a minute or two after the injection. Care should be taken not to make the injection into one of the extraocular muscles or too near the levator muscle. If the injection is given close to the posterior part of the globe and not deep in the muscle cone, fewer muscle palsies occur.

About one hour after the injection chemosis of the conjunctiva and proptosis of the globe develop. This reaction lasts from two days to a week. A partial paralysis of one or more of the extraocular muscles or a ptosis occurs in about 50 to 75 percent of the patients. This complication lasts for a few days to two months depending on the site of the injection. In no instance in this series has a permanent paralysis occurred. Neither neuroparalytic nor dendritic keratitis has occurred in a single case after injection. The patients frequently complain of a feeling of fullness of the orbit for 24 to 48 hours after injection but when the injection has been given properly the ocular pain is relieved. If the injection has not been given correctly and the patient's symptoms are not relieved, the injection can be repeated without danger 2 or 3 days later.

When alcohol therapy was first used at the Wilmer Institute, we were apprehensive about the reactions which might follow, so only 1 cc. of 40- to 50-percent ethyl alcohol was used after an injection of 1 cc. of 2-percent novocain. Pain was not always controlled with this strength solution and the complica-

TABLE 1
RETROBULBAR ALCOHOL INJECTIONS IN BLIND EYES
(Less than 10/200 vision)

Diagnosis	No. of Cases	Diagnosis	No. of Cases
Absolute glaucoma	22	Phthisis bulbi	2
Secondary glaucoma	6	Keratitis after mustard gas burn	1
Parenchymatous keratitis and uveitis	6	Keratoplasty	1
Corneal ulcer	2	Endothelial dystrophy	1

tions were not severe or permanent so 95-percent ethyl alcohol was tried. The results have been more consistent with the stronger solution and the reactions only slightly greater. Therefore during the past four years only 80- to 95-percent alcohol has been used. The blind eyes in which 40- to 50-percent alcohol was given are not included in this report.

ALCOHOL INJECTIONS ON BLIND EYES

A retrobulbar injection of 1 cc. of 95-percent ethyl alcohol was done on 41 eyes with less than 10/200 vision. Many of these eyes would have been enucleated because of pain. A tabulation of the diagnoses in these eyes is given in Table 1. In six patients the pain was not alleviated either because the injection was not given properly or because not enough alcohol was used. Pain was controlled in 35 eyes for at least one month. Eleven of the patients were not seen in the clinic after one month so it is not known whether the pain returned after this time or not. In seven patients the pain returned after two months or longer and the eyes were removed. The remaining 17 patients were followed for two months to three years. In these patients the pain did not return or it returned only intermittently and was not severe enough for the patient to desire enucleation.

Fifteen eyes were removed after alcohol injections affording an opportunity for studying histologically the effect of alcohol injections on the optic nerve. In 13 of these eyes the pain was either not controlled or returned several months after the injection.

TABLE 2
FIFTEEN EYES EXAMINED HISTOLOGICALLY AFTER ALCOHOL INJECTION

Diagnosis		Pain Controlled	Interval Between Injection and Enucleation	Optic Nerve
Absolute glaucoma	(4 eyes)	Not controlled	2 eyes—4 days 2 eyes—1 week	Glaucomatous optic atrophy but no abnormal cellular infiltration
Absolute glaucoma and corneal abscess	(1 eye)	Not controlled	2 weeks	
Absolute glaucoma	(3 eyes)	2 months	2 months	
Absolute glaucoma	(1 eye)	3 months	8 months	
Absolute glaucoma	(2 eyes)	4 months	5 months	
Phthisis bulbi	(1 eye)	Not controlled	1 week	Optic atrophy
Parenchymatous keratitis	(1 eye)	7 months	17 months	Normal nerve
Corneal ulcer	(2 eyes)	1 month	1 month	Normal nerve

In two instances the pain was controlled for one month but the eyes were removed because the patients were elderly; had severe corneal ulcers in one eye, and normal vision in the other eye. The time of removal of these eyes after alcohol injection is listed in Table 2. In the eyes with absolute glaucoma, there was advanced atrophy of the optic nerve but in no case was there a marked cellular infiltration of the nerve or nerve sheath to indicate that damage had been produced by the injection.

In a few eyes removed shortly after in-

will return when the nerves regenerate. Histologic examinations of the optic nerves in 15 cases did not show evidence of injury by the alcohol.

ALCOHOL INJECTIONS ON EYES WITH PARTIAL VISION

Retrobulbar alcohol injections have been done in 15 patients whose final visual acuity ranged between 10/200 and 20/20. The type of ocular lesion, duration of pain before alcohol injection, the amount of alcohol injected, and the visual acuity before and

TABLE 3

RETROBULBAR ALCOHOL INJECTIONS IN EYES WITH PARTIAL VISION
(Final Vision 10/200 to 20/15)

Diagnosis	Duration of Pain	Amount of Alcohol		Vision at Time of Injection	Final Vision and Interval After Injection	
Tuberculous keratitis	8 mo.	1 cc.	45%	1/200	20/50	6 yr.
Epidemic keratoconjunctivitis	3 mo.	1 cc.	45%	20/50	20/20	5 yr.
Epidemic keratoconjunctivitis	4 mo.	1 cc.	45%	20/40	20/20	1 yr.
Uveitis after cataract extraction	4 mo.	1 cc.	95%	10/200	20/100	2 mo.
Uveitis after cataract extraction	5 mo.	1 cc.	95%	20/50	20/15	2 yr.
Disciform keratitis	5 mo.	1 cc.	95%	20/70	20/40	5 mo.
Disciform keratitis	4 mo.	1 cc.	95%	20/30–2	20/20	1 yr.
Disciform keratitis	2 mo.	1 cc.	95%	20/100	20/25	8 mo.
Herpes zoster keratitis	9 days	1 cc. 95% after 2 days 1 cc. 95%		1/200	20/30	6 mo.
Herpes zoster keratitis	11 mo.	1 cc.	95%	4/200	20/100	5 mo.
Postoperative panophthalmitis	8 days	1 cc.	95%	L.P.	20/30	1 yr.
Recurrent corneal erosion	2 mo.	1 cc.	95%	20/200	20/100	9 mo.
Sympathetic ophthalmia in remaining eye	1 yr.	1 cc.	95%	L.P.	20/100	1 yr.
Glaucoma secondary to uveitis	14 days	1 cc.	95%	3/200	20/200	2 mo.
Glaucoma secondary to uveitis	3 mo.	1 cc.	95%	10/200	10/200	6 mo.

jection, there was a slight cellular infiltration of the posterior superficial sclera which might have been caused by irritation from the alcohol. The three eyes removed because of corneal ulcers and parenchymatous keratitis were extremely valuable for they showed no evidence of atrophy or injury of the nerves.

This group of cases indicates that the injection of 1 cc. of 2-percent novocain followed by 1 cc. of 95-percent alcohol will control ocular pain for 1 to 3 months if the injection is given properly. The anesthesia is not permanent, however, and if the primary cause of pain is not remedied the pain

after injection are listed in Table 3. When alcohol injections were first used on eyes with partial vision, we feared that the optic nerves might be injured by this procedure. Therefore, in the first three patients only 1 cc. of 45-percent ethyl alcohol was used after an injection of 1 cc. of 2-percent novocain. Vision was not reduced following this treatment.

During the interval these patients were being followed, 95-percent alcohol was found to be much more effective in controlling pain in blind eyes and histologic examination of several eyes after injections of this strength alcohol failed to show evi-

dence of injury to the optic nerves. We therefore began to use 95-percent alcohol in eyes with partial vision. Twelve eyes have been injected with the stronger solution of alcohol and in no instance has the visual acuity been reduced from this procedure.

CASE REPORTS

The results of alcohol injections in these eyes with vision have been so striking that several of the cases will be described briefly.

The first patient with a potentially seeing eye to be injected had a parenchymatous keratitis with marked photophobia and blepharospasm. The lesion was located primarily in the central portion of the cornea, the pupil would not dilate adequately with atropine, and his vision was reduced to hand motions at two feet. He had not been able to work for eight months because of his pain. An enucleation was considered because his keratitis did not respond to the usual forms of therapy and because of the protracted course of this illness. One cc. of 45-percent ethyl alcohol relieved his pain completely and his pupil became more dilated so that his vision improved to 20/70. It has now been six years since the injection. Vision is 20/70 with a full visual field. The patient has had several minor exacerbations of his keratitis during this interval but none of them have been severe enough to warrant a second alcohol injection.

A second patient had a persistent low-grade anterior uveitis following a cataract extraction. The uveitis failed to respond to antibiotics, typhoid-fever therapy, salicylates, and local atropine. He had been confined to his house and hospitalized for five months. His vision was 20/50 but he requested enucleation for the relief of his pain. A 1-cc., 95-percent alcohol injection completely relieved his pain. During the next three months his uveitis gradually subsided and his vitreous opacities cleared. It has now been two years since his alcohol injection and his vision is 20/15 with a full visual field.

A third patient had a disciform lesion fol-

lowing a dendritic keratitis of four months' duration. His vision was 20/30—2 but he was unable to work for several days each week because of photophobia and ocular pain. A 1-cc., 95-percent alcohol injection relieved his pain. This patient suffered a partial paralysis of the external rectus muscle which caused diplopia for two weeks. The eye was occluded during this interval and the patient was able to return to work. The edema of the cornea subsided during the next two months and the patient now has a small scar in the inferior portion of his cornea. It has been one year since the injection and his vision is 20/20 with a full visual field.

In a fourth patient with herpes zoster keratitis, the first injection of 1 cc. of 95-percent alcohol did not control the pain and a second injection was given two days later. He developed a marked orbital reaction and a paralysis of several of his extraocular muscles which lasted for a month. This patient's visual acuity six months after injection had improved from counting fingers at two feet to 20/30.

In most eyes in this series alcohol injections have had little effect on the basic inflammatory lesions. It has merely relieved the patient's pain while the lesions have undergone their natural process of healing. In four cases of keratitis, however, two which followed epidemic keratoconjunctivitis and two which followed herpetic keratitis, the course of the disease might have been shortened by alcohol injections. In these patients the epiphora and blepharospasm, which might well have been contributing to the continuance of the keratitis, were relieved by the alcohol injections.

In this series of cases injections have not been used to reduce the ocular tension in primary congestive glaucoma as advocated by Weekers and Magitot. It was used in two eyes with secondary glaucoma, however. In one eye the tension was lowered and in the other it was not affected.

In summary, retrobulbar alcohol injec-

tions have been done on 15 patients who have had severe or protracted ocular pain and partial vision. No permanent complications have followed the injections and in most cases the final visual acuity has been better than it was at the time of treatment.

DISCUSSION

Retrobulbar alcohol injections are a valuable adjunct to ophthalmic therapy for the relief of severe protracted ocular pain. The fear of permanent extraocular palsies, neuroparalytic keratitis, and injury to the optic nerve does not seem to be warranted when the method of alcohol injection described in this report is used. No permanent complications have been noted following such injections in 41 blind eyes and 15 eyes with partial vision.

Alcohol injections into peripheral nerves relieve pain by interrupting the transmission of the nerve fibers. The proteins in the fibers are coagulated at the site of injection and the fibers degenerate peripherally from this point. If the nerve is not injected but the surrounding area is infiltrated with alcohol all of the fibers may not be destroyed but transmission is depressed. The peripheral portion of the fibers usually regenerate in a few months after injury by a migration of the axones from the uninjured part of the nerve.

Injections into sensory ganglions, on the other hand, destroy the ganglion cells and cause a permanent anesthesia of the area supplied by the nerve. Permanent anesthesia of the eye is not produced by retrobulbar alcohol injections for the ganglion cells of the sensory nerves from the eye are located in the Gasserian ganglion and not in the orbit.

It is, therefore, not necessary to inject alcohol into the posterior part of the muscle cone near the ciliary ganglion to relieve ocular pain. Infiltration of the more anterior portion of the muscle cone will interrupt the nerve transmission just as effectively and has the advantage of causing less damage to the extraocular muscles.

It is interesting that corneal sensation which is either lost or markedly diminished following the injection of alcohol usually returns to some degree within a few weeks after injection even though the pain is controlled. A similar return of corneal sensation and not pain has been noted after sectioning of the fifth nerve for trigeminal neuralgia.[9] Likewise the sensation of touch returns before pain after injections of other sensory nerves of the body.[10]

The parasympathetic motor nerves to the pupil and ciliary body are interrupted to some extent after retrobulbar alcohol injections. Contraction of the pupil and accommodation, however, return within several weeks.

The optic nerve is apparently protected to a marked extent from the effects of alcohol by its sheath. There was no reduction of vision after the injection of alcohol in 15 eyes with partial vision nor was there evidence of injury to the optic nerve in 15 eyes examined histologically. It is possible that injection of larger amounts of alcohol than were used in this series of patients might injure the optic nerve. The case of Cordes demonstrates that injection of alcohol into the nerve will destroy it. The use of a preliminary injection of novocain should indicate whether the tip of the needle is in the optic nerve or not.

In this series of cases alcohol injections did not seem to have a detrimental effect on the course of ocular lesions. However, in other studies Kornblueth and I have found that corneal transplants do extremely poorly when they are grafted into eyes of rabbits which have previously received retrobulbar alcohol injections. These poor results were not due to an anesthesia of the cornea, for all of the nerves could be sectioned in the periphery of the cornea of the recipient animal and clear grafts could be obtained.

Kornblueth[11] has made further studies on the effects of retrobulbar alcohol injections in rabbits and rats and has found that the rate of mitosis in the epithelial and stromal

cells was reduced. The healing of small lesions in the corneal epithelium was not impaired but the regeneration of the epithelium was definitely impeded when the whole cornea was denuded. This would suggest that retrobulbar alcohol injections might be detrimental to healing of large corneal ulcers.

Weekers and Magitot, however, have advocated the use of alcohol injections for corneal ulcers and have not reported a delay in the healing of these lesions. We have not used alcohol injections in enough cases with corneal ulcers to establish what effect it will have on repair, but the experimental findings in rabbits suggest that it should be used with caution in patients with corneal ulcers. They also suggest that, if a keratoplasty or keratectomy is contemplated, an interval of at least 3 to 4 months should elapse between the time of injection and operation.

Alcohol injections did not reduce the ocular tensions in patients with absolute glaucoma in this study. However, it may be indicated in less advanced cases of glaucoma which fail to respond to medical therapy, for Weekers and Magitot have reported that the tension is reduced in some patients with acute congestive glaucoma, and Kornblueth has found that the ocular tension and rate of formation of the aqueous is reduced in normal rabbit eyes following alcohol injections.

The relief of ocular pain by alcohol injection should not be allowed to influence one in deciding whether an eye should be removed in a patient with questionable sympathetic ophthalmia or intraocular tumor. It should also be established that a patient's pain is real and not imaginary before an alcohol injection is given.

SUMMARY

Retrobulbar injections of alcohol have produced a dramatic relief of pain in 35 patients with blind eyes and in 15 patients with partial vision for at least 1 to 3 months. No beneficial effects have been noted from the alcohol injections other than relief of pain and blepharospasm. Transient extraocular palsies have occurred but no permanent complications such as injury to the optic nerve, extraocular palsies, neuroparalytic keratitis, or sloughing of the cornea have been noted.

ACUTE SECONDARY GLAUCOMA DUE TO SPONTANEOUS RUPTURE OF THE LENS CAPSULE*

H. SAUL SUGAR, M.D.
Detroit, Michigan

Recent experience with three cases of spontaneous lens capsule rupture indicates the importance of this condition in the differential diagnosis of the secondary glaucomas. It was not included in the classification of the glaucomas which I have been elaborating and modifying during the past several years not only because I had never seen such a case, but because of the difficulty of classifying the cause of the increased intraocular pressure.

Two diseases of the crystalline lens must be considered in discussing spontaneous lens-capsule rupture. These are lenticular intumescence and so-called spontaneous absorption of cataract. The first, lenticular intumescence, is ultimately the cause of spontaneous lens-capsule rupture. Intumescence lasting several years leads to thinning of the capsule to such a degree that small rents in the membrane result. In the cases presented here, the cataracts in the involved eyes were present for 8, 10, and 25 years, respectively.

The ophthalmic literature contains many cases in which the lens substance was absorbed through an allegedly intact lens capsule (Hess[1]). In relation to these, cases of spontaneous lens-capsule rupture are few in number. Since the latter involve the anterior capsule, it would be expected that they would be fewer in number than those involving the thinner posterior capsule. The relative numbers of these cases suggest that the cases of spontaneous lens absorption are really cases of posterior lens-capsule rupture. Experience with morgagnian cataracts and lens absorption after perforation of the capsule suggests that the lens cannot be absorbed without capsular rupture and that these cases of spontaneous lens absorption are really due to the presence of dehiscenses in the posterior capsule. It is probable that in posterior capsular rupture the lens material cannot find its way into the aqueous but is held back by the zonular ligament if the particles are large.

The frequent occurrence of glaucoma and iritis in connection with the so-called spontaneous absorption of cataract is further suggestive evidence of the relationship between the absorption of the lens and capsular rupture since the increase in intraocular pressure and anterior uveitis are associated with the capsule tears in the known cases of spontaneous capsule rupture.

Four instances of glaucoma occurred in the 34 cases of spontaneous cataract absorption collected by von Reuss.[2] Natanson,[3] Verry,[4] Gifford,[5, 6] and others reported similar cases.

The first reported case of spontaneous capsular rupture associated with increased intraocular pressure was that of Ulrich,[7] in 1882. Von Szily[8] reported a case and mentioned that of Ulrich and one of von Arlt. Gonzales and Gonzales,[9] Rollet and Genet,[10] Knapp,[11] and Kaufman[12] reported cases of this type.

The cause of the glaucoma in spontaneous lens-capsule rupture is important. Three possibilities are apparent: (1) Chemical irritation by lens substance, (2) increased protein content of the aqueous which tends to lessen the osmotic differential between the aqueous and the blood serum, and (3) obstruction of the trabecular spaces by particles of lens substance.

The first is the only condition which appears to be present in every case. I am, therefore, placing this form of glaucoma in the classification of the secondary glaucomas under the group of secondary glaucomas which are probably due to over-production

1510   H. SAUL SUGAR

of aqueous as a result of irritation of the ciliary processes:

SECONDARY GLAUCOMAS

Each may be subdivided into a noncongestive and a congestive phase. Some never enter the congestive phase.

A. *Secondary glaucomas due to mechanical blockage of the trabecular spaces*
 1. Obstruction by iris
  a. Acute secondary glaucoma due to lenticular intumescence
  b. Acute secondary glaucoma due to dislocation of lens into anterior chamber
  c. Glaucoma following operation for cataract—aphakic obstructive glaucoma—due to delayed reformation of the anterior chamber
  d. Glaucoma associated with essential progressive atrophy of the iris
 2. Obstruction of the trabecular spaces by particulate matter
  a. Glaucoma capsulare
  b. Pigmentary glaucoma
  c. Glaucoma due to obstruction by lens particles
  d. Glaucoma due to tumor growth
  e. Glaucoma due to cellular debris associated with active or healed iridocyclitis
B. *Secondary glaucomas due to lack of communication between the anterior and posterior chambers*
 1. Secondary glaucoma due to seclusion of the pupil
 2. Secondary glaucoma due to total posterior synechia
C. *Secondary glaucomas probably due to overproduction of aqueous as a result of irritation of the ciliary processes*
 1. Glaucoma associated with posterior dislocation of the lens so latter touches ciliary processes
 2. Glaucoma associated with cyclitis and anterior choroiditis
 3. Glaucoma due to spontaneous lens capsule rupture
D. *Secondary glaucomas due to obstruction of venous drainage*
 1. Experimental and clinical glaucoma due to vortex vein obstruction
 2. Secondary glaucoma in pulsating exophthalmos

CASE REPORTS

CASE 1

History. Mrs. R. K., aged 69 years, was first seen by me on July 2, 1948, through the kindness of Dr. Joseph Kopel. She was too uncomfortable to leave her bed. She complained of severe pain in her left eye of two days' duration. The right eye had been successfully operated for cataract eight years previously. The left vision had been obscured by a cataract for nearly eight years and had never been examined during that time.

The right eye was pale, soft, and showed evidence of an iridectomy and aphakia. The left eye was somewhat congested but the anterior chamber appeared clear. The intraocular pressure was 60 mm. Hg (Schiøtz). The anterior chamber did not appear to be particularly shallow. The pupil was not dilated, and showed a hypermature cataract. Physostigmine was instilled and 0.25 gr. morphine sulfate was administered. The pain was relieved and the intraocular pressure was reduced to 32 mm. Hg. Pilocarpine nitrate (2 percent) was ordered for instillation four times daily.

On the following morning the patient began to have severe pain in the left eye associated with nausea and vomiting. The eye was moderately congested and the aqueous was somewhat cloudy, although the cornea was clear. Because of lack of coöperation, slitlamp biomicroscopy could not be done. The patient was hospitalized and an iridectomy-iridencleisis operation was done.

Following the conjunctival closure there was a sudden motion of the contents of the lens which at the time suggested dislocation of the lens. Atropine was instilled. The eye was red on the following day, and the intraocular pressure remained high for a week, during which time a considerable amount of fibrinous material was present in the anterior chamber. Scopolamine and penicillin were used locally.

By July 22, 1948, the eye was much paler. There was no evidence of lens dislocation,

but the lens nucleus could now be seen clearly with little overlying cortex. No perforation of the anterior capsule could be found. Gonioscopically, the angle was open except at the limbus of the coloboma. The tension was within normal limits. Within six weeks after the operative interference the eye was entirely pale.

The diagnosis was not made in this case until the appearance of Case 2, when it was realized in retrospect that this was an instance of posterior lens-capsule rupture. The inability to do slitlamp biomicroscopy delayed proper evaluation of this case. At the onset of symptoms, the anterior chamber was clear by gross observation. The normal anterior-chamber depth and the absence of pupillary dilatation were against the diagnosis of acute glaucoma due to lenticular intumescence.

The subsequent gonioscopic appearance of the chamber angle tends to corroborate this. I can only speculate that a small perforation of the posterior capsule was causing a chemical irritation of the ciliary body producing a type of secondary glaucoma such as appears with cyclitis.

The lowering of intraocular pressure by the use of eserine for a brief time, although it suggests that chamber angle block was relieved, cannot be considered significant, since it was transient and since the angle was subsequently found to be wide and completely free of synechias except at the coloboma area.

The motion of the lens capsule following the operation was evidently a sudden increase in the size of the opening in the posterior capsule so that the liquid cortex was suddenly evacuated. The subsequent course, including the fibrinous iritis and the rapid subsidence with marked thinning of the lens, is evidence of sudden expulsion of the liquid cortex into the aqueous. Since there was no visible anterior-capsule dehiscence at this time or subsequently, a rupture of the posterior capsule must be assumed.

Comment. I have recently had an opportunity to observe the process of absorption of a lens in which the posterior capsule was ruptured. This occurred in a 15-year-old boy who was struck in the left eye on April 29, 1949. The lens was not dislocated but a vertical linear rupture of the posterior capsule was visible. The lens material bulged through the tear giving the appearance of a posterior lenticonus. The lens became opaque in its posterior aspects gradually, and separation of the fibers, with thinning of the lens, occurred. No conjunctival injection remained after the first week. The anterior chamber remained clear during the process. There was no increase in intraocular pressure. The absence of a beam in the aqueous fitted in with the observations in Case 1.

CASE 2

History. Miss A. A., aged 52 years, was first seen on August 17, 1948. She complained of severe pain in her left eye for about one day. She had had a uveitis associated with the formation of a cataract 10 years previously. Tuberculin treatment was used at that time.

Eye examination. The visual acuity was 20/20 with the right eye and light perception with inaccurate projection, left eye. The right eye was entirely normal. The left conjunctiva was moderately injected. The anterior chamber was so cloudy as partly to obscure the iris and lens. No deposits were present on the posterior corneal surface. Particularly noteworthy was the inability to distinguish by optical section the separation between posterior corneal surface and anterior chamber. The intraocular pressure was over 70 mm. Hg (Schiøtz).

A diagnosis of capsular rupture was made and an anterior chamber puncture done with a 27-gauge needle from the temporal side. The aqueous was examined microscopically and found to contain finely granular particulate matter. Scopolamine was instilled.

The eye was reexamined 30 minutes later, at which time the secondary aqueous was quite clear. A morgagnian cataract was present. Two tiny holes in the anterior capsule near the nasal margin of the pupil were

seen. Tiny tufts of lens material protruded through these openings. The eye was treated with scopolamine instillations.

Four days later the tonometric reading was 28 mm. Hg (Schiøtz). A week after this it was 14 mm. Hg. The lens capsule was apparently closed, the cortical material having been evacuated. The eye remained completely quiet for five months. The original picture then recurred. An anterior puncture was done. The aspirated aqueous contained 230 mg. percent protein. The eye became quiet within 48 hours.

Comment. The differential diagnosis of spontaneous capsular rupture may be very difficult, especially since the anterior chamber may be cloudy with anterior capsular rupture and relatively clear with posterior capsular rupture. The history of long-standing cataract with breakdown of the cortex is the necessary background for such an occurrence. Such a history in the presence of increased intraocular pressure should always suggest the possibility of capsular rupture.

With a very cloudy anterior chamber and the above history anterior-chamber puncture may make possible both diagnosis of anterior-capsular rupture and cure of the glaucoma as in the second case reported. From the literature and the experience with these two cases, it is evident that once the liquid cortex is vacuated, closure of the defect is possible.

CASE 3

History. This patient, J. R., a 64-year-old man, was first seen by me on July 6, 1949. He complained of redness and pain involving the left eye, for the previous six days. He had had a cataract in this eye for the past 25 years.

Eye examination. The right eye was entirely normal, with a normal tension and anterior-chamber depth. The left visual acuity was limited to light perception, temporally. The tension was 70 mm. Hg (Schiøtz). The corneal epithelium was hazy. The anterior chamber was of normal depth with some clouding of the aqueous. A morgagnian cataract was present.

An anterior-chamber puncture was done. The aqueous which was removed was slightly opalescent. Biomicroscopic examination immediately after the anterior-chamber puncture showed an outpouring of fibrinlike material into the anterior chamber. No anterior capsular perforation could be seen in the 4-mm.-wide pupil area.

Atropine was instilled daily. The tension was 60 mm. Hg on the next day and 48 mm. Hg on the following day.

Operation. On July 11, 1949, under local anesthesia, a bevelled keratome incision was made 2 mm. from the upper limbus, penetrating the anterior capsule. The milky cortical material was allowed to escape through the wound. A small nucleus filled the pupil area. A cystotome was introduced and the nucleus pushed downward. A Daviel spoon was then introduced and the nucleus broken up by crushing it between the spoon and cornea by using a lens expressor externally. The entire nucleus was removed. The anterior chamber was irrigated.

The capsule was then observed anterior to the iris above. This was removed with a capsule-remnant forceps. No vitreous was lost. The pupil was entirely clear. Atropine was instilled.

On the following day the anterior chamber contained fibrinous exudate and the tension was hard. The wound remained intact and the chamber cleared slowly under atropinization. On the third postoperative day the tension became soft and has remained so, with brief rises to 32 mm. Hg.

CONCLUSION

Three cases of spontaneous capsular rupture with acute secondary glaucoma are reported.

The difficulties of differential diagnosis and the place of the condition in the classification of the secondary glaucomas are considered.

It is suggested that cases of spontaneous lens absorption are due to posterior capsular rupture.

THE RETINAL ARTERIOLES IN COARCTATION OF THE AORTA*

14-YEAR OBSERVATION OF A CASE

BEATRICE W. CONNELLY, M.D., AND GLEN GREGORY GIBSON, M.D.
Philadelphia, Pennsylvania

Coarctation of the aorta, a congenital or developmental partial or complete stenosis of the artery at or near the insertion of the ductus arteriosus, produces an elevation of the systemic blood pressure above the lesion, and relatively normal tension below the level of the constriction. This elevated blood pressure is presumably present in the retinal arterioles. There has not been much ophthalmic interest in this vascular anomaly because there are no ocular symptoms produced by it.

Since the cause of this form of hypertension is most probably a simple mechanical obstruction which increases the peripheral resistance to the flow of blood, uncomplicated by toxic, hormonal, neurogenic, and other unknown factors which operate in essential hypertension, we have at our disposal, in these rare cases, an opportunity to observe the responses of the retinal arterioles to simple increased blood pressure. Since the complicated mechanisms are not completely understood, by which the changes of essential hypertension are produced, it is possible that some information about this process might be forthcoming from the observation of what occurs in the retinal arterioles in patients who have coarctation of the aorta. It is possible, however, that the mechanism of the elevated blood pressure is not simple increased peripheral resistance but that other factors, such as renal ischemias, are operating in these cases.

It is known that there exists a relationship between the degree of the retinal arteriolar changes in essential hypertension and the two factors which seem most important in determining the effect of the hypertension on the patient. Those two factors are the severity and the duration of hypertension. It is also recognized that, in a comparatively

small group of patients with hypertension, the relationship is disproportionate between arteriolar change, on one hand, and severity plus duration, on the other. This disproportion may be either more or less than the amount that is expected.

Ophthalmologists who have studied large series of these patients and correlated the retinal and clinical findings are able to recognize these disproportionate cases. The patient whose record is reported here, represents an instance of this disproportion. It seems reasonable to assume that the disproportion, in this case, between the actual and the expected amount of sclerosis is due to the difference in the mechanisms of the two entities; namely essential hypertension and coarctation of the aorta.

One of the unknown points in hypertension is which comes first, the hypertension or the attenuation or uniform narrowing of the retinal arterioles. It is an unsettled question whether the attenuation is the cause of the hypertension or the result of the hypertension. Likewise, the mechanism of the sclerosis is unknown. While one can draw no conclusions from one case, it would seem that the findings in this case of coarctation offer material for thought on these interesting and important points. There are numerous references in the literature about the retinal changes in coarctation of the aorta and all the findings observed in our case have been recorded as occurring in previously reported cases.

PREVIOUSLY REPORTED CASES

Schwartz,[1] in reporting five cases, found the retinal picture to vary from normal in the mildest case, to tortuosity, spasticity, arteriovenous nicking, and increased reflex stripe in the more severe cases.

Blue,[2] in one case, found minimal early arteriosclerosis of the retinal vessels. Rhodes and Durbin,[3] in one case, reported narrowing and tortuosity. Draper,[4] in a report of one case, found normal fundi as did Shapiro.[5]

Christensen and Hines[6] found that, among 80 patients who had fundus examinations, only 22 had essentially normal fundi. Generalized narrowing of the retinal arterioles was frequent. Higher grades of sclerosis were found in cases when the diastolic pressure was over 110 mm. Hg. No patient had severe hypertensive retinopathy.

Among the many other references are listed fundus findings similar to those herein. These range from normal fundi in cases with little or no hypertension to more advanced changes in cases with hypertension. However, reports of repeated fundal examinations over an extended period of time in the same patients were not encountered in the literature. The justification for this report is that cases of long-time observation on coarctation were not found, and there was no reference to an attempt to correlate the significance of the findings in these cases with the significance of the findings in cases of essential hypertension.

CASE REPORT

History. The patient, a white man, was first examined at the age of 21 years, in June, 1933. The chief complaint was occasional diffuse pain in his legs and lower abdomen for the past four years. The past history revealed that he had also had pain in his legs at the age of 10 years which lasted for three years.

The clinical examination showed a well-developed white male weighing 155 pounds, showing redness of the face and neck. There was no cyanosis and no clubbing of the fingers. A large pulsating vessel was seen and felt in the upper right interscapular region, also on the left side at the level of the first thoracic segment. The subclavian arteries likewise showed marked pulsations. The radial arteries had a slightly increased amplitude, while the femoral arteries could not be felt. The blood pressure was, in the right arm, 200/80 mm. Hg, and 160/95 mm. Hg in the left arm. Auscultation of the heart revealed no significant murmurs and the

heart showed no enlargement.

Electrocardiograms showed a regular sinus rhythm. There was no axis deviation. X-ray examination of the thorax revealed the typical erosions of the under surfaces of the ribs which is commonly noted with coarctation of the aorta. The heart shadow was not above the upper limits of normal size.

The clinical diagnosis was coarctation of aorta, and a fundal examination was requested by the cardiologist, Dr. Roesler.

The external ocular examination, the visual fields, and the ocular media were negative. The fundal examination was negative except for the blood vessels. All the arterioles were more tortuous than normal and two were mentioned as being unusually tortuous. There was a slight accentuation of the reflex stripe on the retinal arterioles. All the arterioles, instead of being larger than normal, showed a moderate attenuation or generalized narrowing of caliber in their entire courses, and this change was very marked in their peripheral thirds. There was no sclerosis, no angiospasm, no pulsation, and no retinitis. The patient would not consent to fundus photography.

Course. The patient was reëxamined in October, 1934, and there were no significant changes. He was reëxamined in June, 1947. He complained of shortness of breath on exertion, dragging of the legs, and occasional epistaxis. He was now aged 35 years and his weight was 190 pounds. The blood pressure was 180/100 mm. Hg in the right arm, and 184/90 mm. Hg in the left arm. The heart was normal in size. The electrocardiogram showed a regular sinus rhythm; there had developed a minor degree of left axis deviation and the initial deflection showed increase in voltage in the chest leads.

The fundus examination was the same with exception that there were now present very slight focal caliber constrictions indicating retinal arteriosclerosis, grade one, on the basis of four, of the hypertensive type.

COMMENT

It is usual in essential hypertension of the degree and duration known to exist in this patient, that one should expect more advanced and severe changes than those which were found. There are two possible explanations for this disproportion, the first of which is the relatively low diastolic pressure. It is well known that the damage to the arteriolar tree is determined not by the height of the systolic but by the height of the diastolic blood pressure. The relatively low diastolic pressure in our patient accounts, in part, for the disproportion between the clinical and the retinal findings.

This fact is somewhat, although not entirely, balanced by the fact that the diastolic pressure in coarctation cases does not undergo the fluctuations nor remissions which occur in many types of essential hypertension. The second possible cause for the absence of more advanced changes is the absence of any hormonal, toxic, or neurogenic influences on the arterioles themselves.

The presence of the severe attenuation or uniform narrowing in this mechanical type of hypertension, where none of the factors which produce essential hypertension are active, would seem to offer strong implications that the attenuation observed in essential hypertension is not the cause of the hypertension but rather represents the reaction of the vascular tree to hypertension.

The criterion for the presence of hypertensive sclerosis in this case are the ones included in Wagener's[7] report on hypertension for the American Ophthalmological Society; namely, the presence of slight focal constrictions or localized areas of caliber narrowing. The marked tortuosity of the main arterioles is matched by the veins and is considered to be a vascular anomaly and is not an indication of sclerosis. This was present in the same degree in the later examination.

The fact that these changes occur in coarctation suggest that sclerosis per se may repre-

sent a further degree of reaction of the arteriolar tree to simple pressure. The fact that the sclerosis is of such slight degree, after such a long duration, suggests that the more advanced changes encountered in essential hypertension are the result of a combination of causes working on the arterioles as well as to higher degrees of diastolic pressure.

It is admitted that the evidence in this one case, and the changes and interferences drawn from this case are not sufficiently convincing to constitute proof of the premises which have been offered but, on the other hand, it seems that their significance is worthy of attention of students of this problem.

SUMMARY

A case of coarctation of the aorta, in which detailed fundus examinations were recorded when the patient was aged 21 and 35 years is reported. On the first examination no sclerosis of the retinal arterioles was present but, 14 years later, there were minimal signs of sclerosis.

It is pointed out that one would expect much more sclerosis to be present than was found on the basis of observations in essential hypertension. There was uniform narrowing (attenuation) of all the arterioles on both examinations.

It is postulated, but not proved that attenuation is the reaction of the arteriolar tree to elevated blood pressure, and that the elevated pressure of essential hypertension produces the attenuation.

Likewise, it seems fair to conclude that sclerosis can be produced by, or is a reaction of the arteriolar tree to, simple elevated blood pressure. The rate and degree of the sclerotic process is increased considerably in the case of hypertension due to higher diastolic pressure and other factors which may be operating in essential hypertension.

ENUCLEATION AND ALLIED PROCEDURES*

PART I: A REVIEW

JACK S. GUYTON, M.D.
Baltimore, Maryland

Removal of an eye by the mutilating and seldom utilized operation of "extirpation," which consists of slashing the eyeball from the orbit without attempting to preserve remaining orbital structures, was rendered obsolete in 1841 by the introduction of "enucleation," a procedure whereby the eye is shelled out of Tenon's capsule. During the succeeding century rather little actual progress was made in the field of eye removal.

True, descriptions of "evisceration" (1872), and of implantation of a foreign material within the sclera (1885), or within Tenon's capsule (1886), led to collection of considerable data as to the relative merits of these procedures with respect to cosmetic appearance, prevention of sympathetic ophthalmia, and prevention of postoperative meningitis. Introduction of the Snellen "reform eye" in 1898 greatly reduced the discomfort and disfigurement so prevalent with the older "shell" prosthesis. Reactions of orbital tissue to various grafts and to foreign substances embedded within it were recorded. Countless descriptions of minor variations in operative technique permitted the sifting out of a few with value. Methods were devised for at least partially correcting deformed or contracted sockets. Introduction of the plastic "acrylic" afforded a lighter, more durable, easier shaped material than glass for making well-fitting prostheses. Finally, recognition that cosmetic defects were likely to follow removal of an eye by any of the methods in use stimulated many ingenious, if largely unsuccessful, attempts to prevent or correct such blemishes.

In 1945 Ruedemann[1] described an artificial eyeball (first used in January, 1941) which he placed in Tenon's capsule at the time of enucleation and to which he actually attached the rectus muscles. He therewith initiated a new era in the enucleation field. In 1947, Cutler[2] described a semiburied implant (his "ring" implant, first inserted in October, 1945) to which the rectus muscles were attached and to which a prosthesis could be coupled after healing of the socket. This two-piece principle made it possible to assure correct orientation of the prosthesis by varying the size and shape of the anterior segment and the position of its coupling pin.

At the Wilmer Institute, utilization of Ruedemann eyes was begun in June, 1945, and of Cutler ring implants in March, 1946. The early cosmetic results were amazingly good, especially with Cutler implants, but a number of these implants extruded some months after successful insertions.

A technique was therefore devised which embodied the two-piece principle of Cutler, but also satisfied an additional new principle. When healing is complete, there is no epithelial-fibrocytic transition at any point, and the "exoplant" is in contact with nothing but epithelium rather than partially buried within tissue; this was accomplished, without any sacrifice of motility, by attaching the recti directly to each other at the juncture of two perpendicular tunnels through the exoplant, there being no actual attachment of muscles or other tissues to the foreign body. With this procedure, epithelium grows completely around the muscles as well as behind the exoplant.

From July 15, 1946, to April 1, 1948, 45 of these exoplants were inserted at the Wilmer Institute. The results have exceeded original expectations. Motility of the prostheses has equalled that obtained with the

Cutler implant; there have been no late extrusions of this exoplant nor late infections around it, and it is suitable for delayed insertion as well as for use at the time of enucleation.

A number of modifications of the semiburied implants embodying the principles of Ruedemann and of Cutler have more recently been devised. The best of these appears to be that of Whitney and Olson,[3] wherein the muscles and Tenon's capsule are attached to a circular strip of tantalum mesh surrounding the implant.

This present report consists of a condensed review of enucleation and related procedures utilized prior to the introduction of semiburied implants with directly attached prostheses (1945), a more complete review of the procedures under development since Ruedemann opened these new vistas, and a description of a new technique involving insertion of an "exoplant" which gives cosmetic results which may prove more uniform and permanent than those attained with any enucleation procedure previously described.

PROCEDURES WITHOUT DIRECTLY ATTACHED PROSTHESES

EXTIRPATION

The first recorded technique for complete removal of the eyeball was described by Bartisch[4] in 1583. Much earlier, Celsus[5] had described obliteration of the anterior segment of the eyeball, and Paré[6] (1579) had advocated excision of unduly prominent staphylomas.

The procedure of Bartisch, "extirpation," consisted in passing a needle and thread through the eyeball and then, while making traction on the thread, passing a knife or sharp-edged spoon into the orbit behind the globe and severing its attachments. This operation was so brutal that Bartolini[7] is cited as pulling out a cancerous eye by hooks, a procedure he considered milder than that of extirpation—although the patient died in convulsions three days later.

It is significant that while Paré,[8] the father of modern surgery, described prostheses as early as 1579 for use after loss of an eye because of trauma or suppuration, he did not mention operative removal of the eyeball. Yet he described such operations as couching a cataract, correcting an entropion, and even restoring a drainage pathway between the conjunctival sac and nose.

Certainly the operation of extirpation was so severe and mutilating it was used only for removal of eyes with cancerous or fungoid growths; globes which were merely painful or suppurating were simply incised and allowed to drain. The severity of extirpation is well illustrated by Bowman's report[9] that from 1839 to 1848 (immediately preceding adoption of "enucleation" as the means of removing an eyeball), only four extirpations were performed at the Royal Ophthalmic Hospital in London, although during that period 1,419 eye operations of all types were performed and 2,302 cases of injury, 23 cases of "fungus of the globe" and 16 cases of orbital tumor were examined.

The dread in which the extirpation operation was held was largely a result of the accompanying pain, since anesthesia was not generally available until about 1850. However, actual mutilation resulted from the complete disregard of the integrity of the orbital structures surrounding the eyeball, leading to a socket generally unsuitable for a prosthesis and consequently cosmetically disfiguring.

SIMPLE ENUCLEATION

Tenon's capsule was first described in detail in 1806, but it then appears to have been forgotten until 1841.[10] In that year, Ferrall[11] and Bonnet[12] independently reëmphasized its significance and proposed the operation of simple enucleation. Ferrall had actually performed such an operation, but Stoeber[13] (1842) is generally credited with popularizing it. This operation consisted of making a circumcorneal incision of the conjunctiva, cutting the muscle insertions without disturb-

ing Tenon's capsule, and cutting the optic nerve close to the globe.

Enucleation did not immediately replace extirpation as the more common procedure, because introduction of general anesthetics about that time made the latter operation far less horrible, though no less disfiguring, than formerly. Not until about 1855 did enucleation come into general use for cases other than malignant growths, especially as a result of Critchett[14] advocating it for cases of staphyloma, intraocular foreign bodies, symblepharon, inflamed and painful blind eyes, and inflamed eyes where sympathetic ophthalmia was feared.

As originally described, no sutures were used following simple enucleation. However, during the succeeding century practically every conceivable type of suture for closing the conjunctiva, and/or uniting two or more of the rectus muscles, and/or closing Tenon's capsule has been described.[15-18] About the close of the 19th century considerable emphasis was placed on the exact methods of closure, but conclusions of different authors were, on the whole, variable. It seems probable that the only suture of real advantage was that which closed the conjunctiva and thus shortened the healing time.

For many years after simple enucleation was first described, minor details of technique were emphasized or argued about and many special instruments (each bearing a proper name) were devised: for example, Landolt's enucleation scissors, Brazil's enucleation knife, Luer's optic-nerve hook, Schweigger's enucleation hook, deWecker's, Terson's, and deWelt's enucleation spoons, and Joseph's hook neurotome. Even in recent years a few descriptions of minor technical details, *rarely original and in no way important*, have crept into the literature.[19-22]

In retrospect, the most important details of technique which have been added to the original decriptions of simple enucleation are those designed to preserve as much conjunctiva as possible. It is generally considered advisable to suture the conjunctiva horizon-

tally because an excess of conjunctiva is available from above and below, but not from each side, for covering the space previously occupied by the cornea. In the presence of preoperative infection no sutures should be used.

Insertion of a conformer at the time of enucleation is of definite value in preventing contracture of the conjunctiva, as well as in preventing conjunctiva from prolapsing between the lids should moderate postoperative hemorrhage occur within the orbit.[23] Should postoperative infection occur, it is especially important that a conformer with a large central opening be kept in the socket to prevent contracture.[24]

SIMPLE EVISCERATION

Evisceration of the globe with retention of the sclera was first described as a deliberate procedure by Noyes[25] in 1872. He merely incised the anterior aspect of the globe and wiped out all contents except cornea and sclera. Graefe,[26] in 1884 advocated evisceration as preferable to enucleation as a means of obviating danger of meningitis from cutting the optic nerve in the presence of a purulent infection. Graefe removed the cornea as well as the intrascleral contents.

In 1898 Hall[27, 28] described an addition to simple evisceration which consisted of removal of a disc from the posterior sclera together with a small piece of optic nerve, after excising the cornea and wiping out the intrascleral contents of the globe. Gifford[29] (1900) advised leaving the cornea intact in order not to reduce the amount of available conjunctiva, and stated that "evisceration" was a misnomer unless the cornea was left intact. Nicati[30] advocated removal of all sclera posterior to the attachments of the rectus muscles, scooping out the anterior segment, and leaving the cornea intact.

Gifford[31] (1914) later reported using a pressure bandage to flatten the corneoscleral envelope after evisceration, thereby obtaining as a stump a large flat disc which was quite satisfactory from the standpoint of the

prosthesis. Dimitry[32] redescribed the Hall operation, and shortly afterward[33] advocated sewing the anterior and posterior lips of the sclera together to give a flat stump.

Lister[34] advised removal of all the sclera except a frill around the optic nerve when evisceration was performed because of pan-ophthalmitis, thus cutting down the prolonged healing time incident to suppuration of the anterior portion of the sclera. This procedure was again advocated by Weve[35] in 1939. Khramelashvili[36] advised opticociliary neurectomy at the time of simple evisceration as a means of reducing postoperative reaction.

ENUCLEATION OR EVISCERATION WITH IMPLANTATION

In 1885 Mules[37] reported burying hollow glass spheres within the scleral envelope at the time of evisceration. He removed the cornea, inserted the implant, and sewed the sclera vertically and the conjunctiva horizontally. Out of the nine cases he originally reported, the implants had to be removed or were extruded in four and in one other there was a fistula at the site of the scleral incision.

Mules initiated his operation with the idea of utilizing the implant to take up space formerly occupied by the ocular contents and thus prevent sinking in of the socket and also to have a stump which moved as well as a normal eye. When he reported this work, before the Ophthalmological Society of the United Kingdom, he demonstrated a patient on whom he had performed this operation. In the discussion, Frost commented that he could see no better movement of the prosthesis than after simple enucleation, although the stump itself moved perfectly.

In 1886 Frost[38] reported burying hollow glass spheres within Tenon's capsule at the time of enucleation. He performed this operation on six patients, but the implant was retained in place in only one instance. In 1887 Lang[39] independently reported a similar

operation with implantation of glass, celluloid, or hollow silver balls. Out of 16 cases, the implant was retained in place in 14. He advocated this procedure because he believed the cosmetic results were better than after simple enucleation and he preferred it to Mules's operation because it gave less postoperative reaction, pathologic specimens were not damaged, and complete removal of the globe obviated the possibility of late development of sympathetic ophthalmia.

During the years succeeding the reports of Mules, Frost, and Lang, the literature became redundant with reports of varied techniques for insertion of implants either into Tenon's capsule or the scleral cavity, with descriptions of implants of various materials and of different sizes and shapes, and with arguments as to the relative merits of theses types of operations as compared with each other and as compared with simple enucleation and simple evisceration.

As the years passed, improved techniques gradually reduced the percentage of implants which were extruded. Thus Verrey,[40] in 1898, collected 343 cases of Mules's operation with extrusion of the globe in 21.3 percent, while Burch,[41] in 1944, reported failures in only 9.6 percent of 52 operations.

Huizinga[42] (1900) described what was essentially Mules's operation but with removal of a disc of sclera from the posterior aspect of the globe along with a portion of optic nerve, and implantation of a fenestrated aluminum ball. He believed removal of the posterior disc reduced postoperative reaction, a view which was later expressed by Ray[43] and by Dimitry.[44] Fox[45] advised tenotomizing the recti as an addition to Mules's operation. He believed this reduced the incidence of extrusions of the implant.

Dimitry at one time preferred leaving the cornea intact in performing Mules's operation, but he soon afterward condemned this procedure because of late thinning and often eventual rupture of the cornea.[33] O'Connor[46] advocated retention of the cornea, with cruciate incisions through cornea and sclera,

and closure by suturing the apices of the corneal incisions and then covering the cornea with a conjunctival flap. Poulard[47] likewise retained the cornea, and implanted ovoids instead of spheres in those cases where he did not retain the cornea.

Burch[48] described his technique as consisting of making a scleral incision around two fifths of the circumference of the globe and just anterior to the superior rectus, removing the intraocular contents, wiping the endothelium off the back of the cornea, inserting a hollow gold ball (usually 18 mm. in diameter but varying from 14 mm. to 20 mm.), and closure of the incision with six fine white silk mattress sutures. This procedure was followed by moderately severe reaction with protrusion of edematous conjunctiva in about half the cases, but Burch believed the reaction was less marked than with the original Mules's operation. The cornea became vascularized in 3 to 6 weeks, but it did not become completely opaque, and Burch did not note thinning or late perforation of the cornea as occasionally described by others.[49]

The size of an implant to be inserted after evisceration must depend on whether or not the cornea is preserved. The implant should not fill the scleral envelope completely, because allowance must be made for some contracture. In general, the implant should be 10 to 14 mm. in diameter if the cornea is removed, or 14 to 18 mm. in diameter if the cornea is retained.

For implantation within Tenon's capsule, Frost originally united the inferior and superior rectus muscles with a silk suture, the same stitch including the overlying conjunctiva, and used another suture to unite the internal and external recti and conjunctiva. Lang also included Tenon's capsule in the sutures. Many variations in the technique of closure have been reported. Verhoeff[50, 51] closed Tenon's capsule by means of a double-armed, 3–0 chromic catgut suture passed successively through both layers of the capsule just in front of the retracted end of each severed rectus tendon, and closed the conjunctiva horizontally.

Berens[52] advocated closure of Tenon's capsule by means of a silk suture which is tied outside the conjunctiva and is removed after healing is complete. Other variations in closure have included closing Tenon's capsule with a purse-string suture, uniting the severed ends of the recti over the then-closed Tenon's capsule, and closing the conjunctiva in still a third layer.

Kirby[53] stressed the care which must be taken not to cut Tenon's capsule, because of the resulting danger of the implant becoming displaced outside the capsule and thus outside of the muscle cone. Kirby[54] also advised closure by overlapping Tenon's capsule obliquely instead of vertically and horizontally.

The percentage of extrusions of implants buried in Tenon's capsule has been found to be minimized by careful attention to the following details: (1) Waiting for complete cessation of bleeding before insertion of the implant, (2) selection of an implant which is never larger than 18 mm. in diameter, with a 14 mm. implant probably the optimum,[55, 56] (3) firm closure of Tenon's capsule and of conjunctiva in separate layers, (4) rigid asepsis, and (5) introduction of a conformer into the socket at the close of operation. Displacement of the implant outside of the muscle cone, even though it is not extruded, has been found to occur all too frequently if Tenon's capsule is ruptured and/or if too large an implant is inserted. Such displacement of an implant is certainly far more detrimental to the cosmetic result than insertion of no implant at all.

After implantation following either evisceration or enucleation, a round stump results, the prominence of which depends on the size of the implant used. If it is very prominent, a shell artificial eye serves best, but if a small implant is inserted and the stump is not prominent, a reform eye is used.[55]

. The different implants which have been described are legion. These include: hollow

silver ball,[57] sponge[58, 59] aluminum frame or fenestrated ball,[60] ball of silk,[61] rubber ball,[62] agar-agar,[63] paraffin ball,[64-66] liquid paraffin,[67-70] autogenous cartilage graft,[71, 72, 219] preserved cartilage,[73] autogenous bone graft,[74] charred bone sphere,[75 76] autogenous fat graft,[77-80] hollow gold ball,[52, 81] preserved tendon,[82] hollow glass in the form of either a sphere or an ovoid, or a grooved sphere,[37, 39, 47, 83] polyviol[78, 84] (a soft plastic which causes considerable tissue reaction), acrylic[85-90] in the form of a solid or perforated sphere or pyramidal shaped, or designed so the rectus muscles can be sutured to it, hollow vitallium sphere,[91] perforated tantalum sheet in four-leaf pattern bent into cup shape,[92] celluloid sphere,[39] and dental wax.[44] In addition, freshly enucleated rabbit eyes have been sutured in place of enucleated human eyes,[93-95] and autogenous grafts of skin and subcutaneous fat have been sutured to the muscle tendons, leaving the epithelial surfaces of the grafts exposed.[96]

At present, the materials most suitable for making nonabsorbable rigid implants of inert material are vitallium, tantalum, or acrylic (completely polymerized methyl methacrylate). These materials stimulate the formation of a minimum of surrounding connective-tissue membrane. Gold and glass cause somewhat more fibroblastic proliferation, but not an excessive amount, and are almost as good for buried implants. There is no necessity for using any of the other materials which have been described for this type of implant. It was probably fortunate that Mules, Frost and Lang selected hollow glass spheres for the first implants, because buried glass does not result in a chronic inflammatory reaction inducive to extrusion of the implant. Hollow glass implants are theoretically objectionable in that they might break within the orbit but such accidents are so rare as to be negligible. I can find only one actual report of such an occurrence,[97] but Dr. Clyde Clapp has observed one additional case.[95] In Dr. Clapp's case the implant broke as a result of a blow by a fist; removal of the fragments of glass was laborious but no serious damage resulted.

Pure polyethylene plastic[99] causes as little tissue reaction as any substance known, and should serve best where it is desirable to have a flexible implant which can be molded at the time of the operation.

Implants prepared from animal or human tissues act only as foreign bodies unless they are autogenous grafts, and are in no way desirable. Preserved cartilage, for example, causes a foreign-body reaction and is gradually absorbed.[73] Charred bone (such as Guist's bone spheres) causes considerable tissue reaction ,and O'Brien[100] has reported he had to remove every one he ever inserted because of late erosion anteriorly through the tissue.

Of the various autogenous grafts generally used for burying in the orbit, the amount of eventual absorption is as follows: with fascia lata, almost none; with cartilage, very little but somewhat variable; with dermis, 30 to 40 percent; and with fat, about 60 percent. Cartilage is probably best in that it is rigid, remains viable when implanted, and undergoes little or no absorption; however, tolerance of the orbit for buried implants of the inert materials is so good it seems needless to perform the additional surgery required to obtain cartilage or any other tissue for an autogenous graft.

PROSTHESES

The earliest artificial eyes about which we have information[101] are those in Egyptian mummies. These are of many varieties, such as silver covered with enamel, or marble with colored glass inserts. Aztec and Inca mummies also often have artificial eyes, as do some Greek statues. Mention is made of artificial-eye makers in old Roman literature. However, the first definite mention of artificial eyes being worn by human beings is by Paré[8] (1579). He described and illustrated oval shell prostheses made of gold and silver,

painted and enameled, designed for wearing beneath the lids.

Venetians are credited with making the first glass eyes in 1619.[102] These eyes were molded and were made to order for each individual case. The Venetians' technique was exposed in 1749, and subsequently a few families, especially in France, developed this art and retained what knowledge they gained as family secrets.

Goudard[103] credits a glass blower of Nevers with making the first blown-glass prosthesis in 1740, but Dimitry[102] credits Sauzay with first describing blown-glass eyes in 1867. "Shell" eyes, made of a single layer of glass with relatively sharp edges, were the only ones available until 1898, when Snellen[104-105] first had his "Reform-Augen" made. These eyes consisted of a double shell with a hollow space between the shells and smoothly rounded edges. They represented two advances in the making of artificial eyes: the rounded edges did away with much discomfort, and the prostheses could be made as thick as desired for filling out deep-set sockets. "Shell" eyes were thereafter rarely used except to cover disfiguring or shrunken eyeballs, or in sockets with very prominent stumps.

The Mueller brothers of Wiesbaden began making artificial eyes under the direction of Snellen in August, 1898. Thereafter, most artificial eyes were obtained by choosing the best fit and match from stock collections.[106-107]

Glass eyes have certain inherent faults. A lead-glass prosthesis may last only nine months to two years because of some erosion of the glass by the lacrimal secretion.[108] Soda-glass eyes are more durable, but very fragile. As early as 1863 Davis, an artificial eye maker in this country, stressed the importance of not only obtaining an exact individual fit but also of discarding a prosthesis as soon as it developed any rough surface.[109] Continuation of wearing a glass eye after its surface begins eroding has resulted in much discharge, conjunctival ulceration, and subsequent contracture of the socket, as well as needless suffering.[110]

Hayes[111] collected 14 reports of "explosion" of reform eyes. Such an "explosion" consists of a break occurring in the posterior shell and a sucking in of orbital tissue because of the relative vacuum (approximately one-half atmosphere) within the prosthesis. Such on occurrence is frightening to the patient but is not serious.

Finally, glass eyes can be made to fit a misshapen socket only by an expert glass blower. Thier[112] described a method of actually molding the socket and making the glass prosthesis the same shape as the mold, but such a procedure was not adaptable to very widespread use.

Since 1944, glass eyes have been largely replaced by plastic prostheses of methyl methacrylate.[108, 114-122] Such eyes were only occasionally made[113, 123] before widespread production of them was first begun in that year by dental technicians in the United States Army.

A number of variations in technique may be used for making acrylic prostheses, but the general plan is as follows: An iris disc is made by painting a transparent disc (composed of ethyl cellulose, smooth water-color paper or glass) with permanent pigments, or by utilizing a photographic reproduction of a real iris. This disc is incorporated in a clear acrylic button the shape of the cornea and the anterior chamber. If a large stock of such buttons is available, a direct match can be selected for the fellow eye. Otherwise the iris disc is painted individually to match the other eye. This button is then invested into an acrylic sclera, which may be selected on the basis of stock sizes and shapes or may be prepared from an actual mold of the socket. Opacity of the scleral plastic is obtained by mixing in some titanium oxide for the whitish background and mixtures of red, blue, and yellow pigments to give the desired color. Blood vessels are reproduced on the

scleral portion with red pigment or etching ink, and sometimes red rayon threads. A clear layer of acrylic is then applied and polymerized or "cured."

A great advantage of acrylic prostheses is that they may be ground down to attain the best fit possible. If the prosthesis is shaped from an actual mold of the socket, alterations in shape toward the conventional form are often necessary. Meticulous care must be taken to polish every surface of the acrylic prosthesis.

Disadvantages of the plastic eye consist in its tendency to scratch if handled roughly, and in the occasional hypersensitivity which may develop to the plastic. The occurrence of allergy for methyl methacrylate is reported to be as common as 1 out of 100 or as rare as 1 out of 10,000.[124, 125] Incomplete polymerization is believed to be of importance in the development of such hypersensitivity.

In cases where destruction of the orbital contents is so marked that a prosthesis cannot be retained by the lids it can only minimize, never obviate, the cosmetic defect. The mutilated socket can often be concealed less conspicuously with a plain flesh-colored patch than with a prosthesis shaped and colored like lids and an immovable eyeball. However, prostheses made to cover the entire orbit will often result in a fairly satisfactory appearance. Such prostheses can be made from wax,[126] but are more easily made from latex.[127-130]

For preparation of a latex prosthesis, an impression is taken of the opposite eye and normally opened lids, and a thin prosthesis is cast from latex which has been colored to match the skin. The markings of the eyeball are then painted on and artificial lashes are attached. Latex prostheses shrink with time and the pigments become discolored, so it is usually necessary to recast such prostheses about once a year. These prostheses are extremely light in weight and can be held in place by attachment to ordinary spectacles or

by a small metal band partially encircling the head.

RESULTS OF ENUCLEATION AND EVISCERATION, WITH AND WITHOUT BURIED IMPLANTS

A. DANGER OF MENINGITIS

Cutting the optic nerve during enucleation affords a potential pathway via the meninges of the optic nerve to the meninges of the brain. Evisceration was originally introduced to obviate danger of meningitis in those instances where the eye was removed because of panophthalmitis, and evisceration has been repeatedly advocated for such cases.[131] However, the actual occurrence of meningitis following enucleation is rare. Out of 10,743 collected cases of enucleation reported in 1898,[132] there were only seven deaths from meningitis, all ocurring in cases with panophthalmitis. Out of 768 collected cases of evisceration there were no instances of meningitis.

DeSchweinitz[133] (1900) collected 478 cases of evisceration with no deaths and 2,875 cases of enucleation, of which 273 were for panophthalmitis, with only one death. Out of 52 cases of panophthalmitis with death from meningitis which he collected from the literature, 33 followed enucleation. Proof was lacking that those cases of meningitis occurring after enucleation resulted from the operation rather than in spite of it. No large scale statistics are available as to the occurrence of meningitis following evisceration, but that it can occur is illustrated by the fact that Schuleck[134] had two deaths out of 36 eviscerations.

In the reported cases of meningitis following enucleation, thrombosis of the cavernous sinus has been frequently mentioned. This fact raises the question as to whether meningitis was actually the result of bacteria entering the optic nerve sheaths or whether it resulted from the surgical trauma to infected orbits. If the latter is the usually correct answer, it would be better to perform

simple evisceration rather than the frill operation advocated by Lister and Weve.

In either event, in these days of available antibiotic therapy, it seems probable that fear of meningitis should rarely influence a decision as to whether enucleation or evisceration is to be performed.

B. Danger of sympathetic ophthalmia

In a majority of the reported cases of sympathetic ophthalmia following any form of eyeball removal, there are grounds for suspicion that sympathetic ophthalmia might have developed if no operation whatever were performed or that it was already present in a clinically unrecognized stage at the time the eye was removed. Nevertheless, there are adequate reports in proof that evisceration will not always prevent sympathetic ophthalmia if the eviscerated eye is potentially sympathicogenic, and that evisceration can rarely result in sympathetic ophthalmia even if the eviscerated eye was itself in no way dangerous.

Thus, deSchweinitz[133] (1900) collected 317 cases of Mules's operation with sympathetic ophthalmia occurring afterward in six instances, and in one case (that of Carrow) the original condition excluded the possibility of its having originated the sympathetic ophthalmia.

Gifford[135] (1908) collected 18 cases of probable sympathetic ophthalmia after evisceration. Nine of these cases occurred after simple evisceration and nine after Mules's operation. Most of them occurred two weeks to a year after the evisceration. Gifford was able to collect only three cases of possible sympathetic ophthalmia following enucleation, and none of these cases is really convincing.

Holdener[136] (1930) reported five cases of possible sympathetic ophthalmia following enucleation, all occurring in patients who had suffered perforations of the globe 14 to 29 days before the eye was removed. In these cases an anterior uveitis developed in the other eye between 18 to 35 days after enucleation, but in each instance the iritis was very mild and healed without loss of vision within a few weeks.

Dor[137] found a much higher incidence of subjective symptoms of photophobia, and so on, in patients who had had eviscerations than in those who had had enucleations.

Advocates of evisceration have from time to time stated the belief that this operation does not cause sympathetic ophthalmia more often than does enucleation.[138] Nevertheless, on the basis of reported cases, it must be concluded that sympathetic ophthalmia is a definite, although small, possibility following evisceration[139, 140] and that it probably never actually begins following enucleation. This fact must be weighed as definitely against evisceration in determining which method should be utilized for removal of the eye.

C. Cosmetic appearance

Cosmetic appearance after removal of an eye must be judged on the basis of appearance and movement of the prosthesis rather than on movements of the stump, as was emphasized by Noyes in his discussion of Mules's original report. Most reports concerning the cosmetic results of enucleation and of evisceration agree that motility and appearance of the stump are best after evisceration with implantation, second best after either simple evisceration or after enucleation with buried implant, and poorest after simple enucleation.

However, appearance and movement of the prosthesis bears rather little relationship to the motion of the stump because of lack of transmission of movements of the stump to the artificial eye. The artificial eye simply rests in the conjunctival sac, being held in place by the lids. It derives its movements from retraction of the various fornices, by contraction of different rectus muscles with simultaneous relaxation of the opposing muscles. The stump itself simply slides

around beneath the prosthesis. One exception occurs in sockets with prominent, convex stumps which will support shell eyes similar to contact lenses,[141] but the attainment of such stumps is uncommon. The degree of actual prominence must be exact if the stump is actually to support the shell and still not result in apparent proptosis.

There is no uniformity of opinion as to which procedure results in best motility of the prosthesis. For example, deSchweinitz[133] preferred simple enucleation, Gradle[142] preferred evisceration with implant, Dimitry [113, 114] preferred each of the procedures under discussion at one time or another, and Gougleman,[110] who actually had the task of fitting prostheses, expressed no opinion except that a small ball implant usually gave a better result than a large implant.

Retraction of the upper lid sulcus is perhaps a more noticeable cosmetic defect after removal of the eye than is poor motility. Some degree of sinking of the upper lid is apparent in all cases except those with deep-set eyes. This sinking of the upper lid has been blamed on various factors, but recent experience with prostheses attached to partially buried implants (sinking of the lid rarely occurs after these procedures) seems to prove the sinking is due to the fact that the weight of the prosthesis is supported by the lower lid and that it therefore tends to push the lower lid outward and downward and to tilt backward in its upper periphery, affording improper support to the levator. It cannot be made large enough properly to support the upper lid without pushing the lower lid so far downward as abnormally to widen the palpebral fissure. A flange or ridge on the upper edge of the prosthesis sometimes will reduce the upper lid sulcus, but more often it will produce a staring expression more repulsive than the deep sulcus, as well as reduce motility.

It is rather generally conceded that abnormal deepening of the upper lid sulcus is minimized by insertion of an implant at the time of enucleation or evisceration. However, Gougelman warns against too large an implant on the grounds that a fuller eye than normal is less pleasing than a small or deep-set eye, and that if the stump is too large it is neither possible to keep a normal fold in the upper lid nor to prevent an appearance of unnatural fullness.

Years after prostheses have been worn, there is not infrequently a relaxation of the lower lid with exaggeration of the depression in the upper lid, a backward tilting of the prosthesis, and even loss of the lower fornix with inability to retain any prosthesis in place.

A good cosmetic appearance is probably best obtained after either evisceration or enucleation if a small or medium-sized implant is incorporated in Tenon's capsule or the sclera, and the results are approximately equal following carefully performed operations of either type. However, all patients who have undergone one of these operations have at least some restriction in motility of the prosthesis, and all except those with prominent brows and deep-set eyes have some degree of displeasing sinking in of the upper lid sulcus.

Alt[143] even advised Green's[144] procedure of removing all conjunctiva, tarsi, and lid margins and sewing the skin of the lids together (complete ablation of the socket) as preferable for most working people on the grounds that the plain skin-covered socket did away with all socket irritation and discharge and was often less conspicuous than a socket containing a prosthesis.

Enucleation during early childhood is rather commonly believed to interfere more or less seriously with orbital development. For example, Vorisek[145] described a man with a very small disfiguring orbit which he blamed on removal of the eye at the age of two years. However, recent studies[144-148] have shown that while a measurable defect in bony development occurs if the eye is removed before the age of five years, and possibly even up to the age of 18 years, this deficiency in development is only in the or-

der of 0.5 to 2.5 mm. in orbital height and width, with slight overgrowth of the maxillary antrum. The defect is not cosmetically apparent. Those cases with implantations showed slightly less deficiency in orbital development than those with no implantations.

PROCEDURE FOR CORRECTING COSMETIC BLEMISHES AFTER REMOVAL OF THE EYEBALL

A. RETRACTION OF UPPER LID SULCUS

In cases with sunken sockets, where retraction of the upper lid sulcus is most likely to be very disfiguring, a few ophthalmologists have considered it advantageous to increase the volume of the orbital contents by late implantations. Suker[69] prepared a pocket in the center of the socket about 3 mm. below the conjunctival surface, injected paraffin into this pocket, and sutured the overlying flaps firmly together.

Fox[45] prepared a pocket within the central stump via an incision in the upper temporal aspect of the socket and implanted a 12- or 14-mm. gold ball. Grimsdale[15] believed late implantation of a glass sphere would occasionally improve appearance but would never improve motion of the prosthesis.

Wheeler[83] described a grooved hollow glass implant with an anterior-posterior diameter of 18 mm. for delayed implantation within the muscle cone. He incised the conjunctiva horizontally and dissected it up rather widely, made a vertical incision through the fibrosed mat of collapsed Tenon's capsule, carried this incision down almost to the apex of the orbit, and inserted the implant so that the rectus muscles (if identified) fitted in the grooves.

DeVoe[149] found late implantation of a glass ball was frequently difficult because the muscles pursued an eccentric course as a result of the scarring following enucleation, that it was usually impossible to implant a sphere larger than 16 mm. in diameter without its extruding either anteriorly or posteriorly, and that such implantation did not

improve movement of the prosthesis and would improve the unsightly retraction of the upper lid sulcus only slightly if at all.

Dimitry believed the cause of retraction of the upper lid sulcus was attachment of the inferior rectus to the superior rectus following enucleation; contraction of the inferior rectus, he supposed, would pull the superior rectus downward, thus indirectly pulling the levator and septum orbitale downward and backward because of the partial attachment of these structures to the superior rectus sheath.[150] Because of this theory, DeVoe[149] tried carefully severing the attachments of the superior rectus from the levator at the time of enucleation, but he found the end results were not improved.

Correction of an abnormally deep sulcus in the upper lid has been accomplished by insertion of a buried graft or implant directly within the upper lid. Smith[151] and Devoe[149] employed dermal grafts, Cutler[152] preferred fascia lata strips, Vannas[152a] used autogenous cartilage, and Sugar and Forestner[153] advocated individually shaped acrylic implants varying from 27 to 30 mm. in length and 5 to 8 mm. in width. The graft or implant is placed between the septum orbitale and the orbicularis, just below the brow, and should arch around so as to fill out the upper lid sulcus in as normal a pattern as possible. Cosmetic improvement has been reported as being uniformly worth while. The defect should be corrected as closely as possible at the time of the operation if an acrylic implant or an autogenous fascia lata graft (which do not absorb) is used, but the defect should be overcorrected if a partially absorbable autogenous graft such as dermis (which eventually absorbs by 30 to 40 percent) is used.

Surprisingly, I have been unable to find any mention of tightening the lower lid for the primary purpose of restoring a normal upper lid sulcus. Certainly tightening the lower lid to hold the prosthesis upward and not tilted backward, thereby supporting the levator and septum orbitale, is a logical and

comparatively minor procedure. It does not induce abnormal widening of the palpebral fissure. The results of such a procedure can be determined preoperatively by pinching the skin just lateral to the lower lid into a vertical fold while the prosthesis is in place. I have never seen this procedure used except where actual ectropion was present, but the results in terms of appearance of the upper lid were so good I believe it should be used rather commonly for its effect on the appearance of the upper lid alone.

B. RELAXATION AND ECTROPION OF LOWER LID

Relaxation or actual ectropion of the lower lid, with difficulty of even retaining a prosthesis in place, is best corrected by a lid-tightening operation such as the Kuhnt-Szymanowski.[74, 154]

C. CONTRACTED SOCKET

Partial contraction of the socket may result from wearing no conformer or prosthesis following enucleation, the subjunctival tissue gradually becoming slightly fibrosed and rigid instead of retaining its normal elasticity.[74] However, in such instances the socket can be gradually enlarged to normal size by the wearing of increasingly large conformers, even if the eye was removed many years previously.[155, 156]

More extensive contracture of the socket may result from wearing a prosthesis with a rough surface so that ulceration and gradual scarring of the conjunctiva take place. Even greater contracture may be encountered in sockets where eyes have been removed because of severe infection with conjunctival ulceration or because of trauma from chemical, thermal, or mechanical causes.

If the contracture is not so extensive as to preclude the retention of a very small conformer, and if there is not too excessive subconjunctival scarring, the socket can often be reformed by using increasingly large conformers. Another procedure at times effective consists in strapping or splinting a

normally large prosthesis into the orbit, with application of pressure to the prosthesis (via a pin attached to its anterior apex) for at least two months.[157]

For restoration of sockets so contracted that small conformers cannot be retained, various plastic operations have been devised, most of them dependent on skin grafts.

Free skin grafts are of three varieties: (1) Ollier-Thiersch grafts, first taken by Ollier with a needle and later by Thiersch with a razor, theoretically purely epidermal but actually including a small amount of dermis, (2) split-thickness grafts including epidermis and one half to two thirds of the dermis, and (3) whole-thickness grafts including epidermis and all of the dermis.

The thinner grafts vascularize more quickly and are more likely to remain viable. With a free graft there is more contracture than with a sliding or pedicle graft, and even with a pedicle graft there is a tiny bit of contracture from scarring along the plane of junction of graft and underlying tissue.[158]

Maxwell[159, 160] first described an operation for forming a lower cul-de-sac and increasing the vertical diameter of the socket (by 4 mm.). His operation consisted in preparing a crescent-shaped skin flap, with the upper margin 5 mm. below the lower lid border, and 8 mm. wide in the center, left attached to the subcutaneous tissue in its center; this was inverted through an incision extending through the lower lid, from the upper edge of the flap into the lower part of the socket, so that the epithelial surface could be sutured to the edges of the conjunctival incision.

Schwenk[161] used Maxwell's method for restoring the lower cul-de-sac and, in those cases where almost all of the conjunctiva was lost, also employed a pedicle flap from above the brow for restoring the upper cul-de-sac.

Weeks[162] used a full-thickness skin graft to restore either the lower or upper cul-de-sac. He inserted a rubber mold at the time of operation and overcorrected the defect about 50 percent. Disadvantages of this pro-

cedure consisted in undue thickening of the lid because of the thickness of the graft, often an unpleasant discharge with some odor, and growth of hairs from the graft.

Czapody,[163] in 1935, again advocated use of full-thickness grafts, and kept the cul-de-sacs stretched postoperatively by means of a two-piece form which could be spread like the blades of a speculum. Lugossy,[164] however, criticized the Czapody operation because late scarring often resulted in an immovable and very disfiguring appearance of the lids.

Esser[165-167] introduced his "epithelial inlay" in 1916, and was the first to describe use of a Thiersch graft for replacement of conjunctiva in contracted sockets. His procedure consisted of full dissection of upper and lower cul-de-sacs and insertion of the graft wrapped around a mold of dental stent.

Esser's procedure has been redescribed many times with minor variations[168-179] and is still the most commonly used operation for restoring severely contracted sockets.

Several details of technique which have been emphasized are worthy of mention.

Dissection beneath the lids should be kept very superficial in order not to end up with lids which are too thick; all scar tissue and granulation tissue should be removed and, if tarsal conjunctiva is involved, the tarus should be split and thinned to reduce the resulting thickness of the lids. The dissection should be carried down one-fourth inch below the infraorbital ridge, up to the levator and one-half inch to each side of this muscle. The graft should be as thin as possible and 50 percent larger than the defect.

The epithelial surface of the Thiersch graft is usually kept against the mold or conformer either by suturing the graft around the mold or by sticking it on with rubber cement, but the graft margins may be sutured directly to the edges of the defect.

A conformer or prosthesis should remain in the socket at least three weeks, keeping the cul-de-sacs stretched. Various conformers of rubber, latex, or acrylic have been advo-cated in place of a mold of dental compound. Flexible conformers such as one simply cut from a hollow rubber ball[174] are probably best, because these can be quite large and yet can be inserted without a canthotomy. After healing is complete, small blisters will indicate the positions of occluded lacrimal ducts, and these can be opened with a hot needle to allow a moist socket.

O'Connor and Pierce[170] advocated use of any available conjunctival flap from elsewhere in the socket, or otherwise a very thin bipedicled skin flap from the upper lid, to replace tarsal conjunctiva of that lid, because a Thiersch graft over the upper tarsus often contracts sufficiently to buckle the upper tarsal plate and concentrate the cilia in the center of the lid.

A combination of skin and mucous membrane as a lining for the socket has most generally been condemned, but Marcks and Zugsmith[74] have recently reported obtaining more flexible sockets by leaving a central area of intact conjunctiva if any is available, or, in case there is no conjunctiva, using a two-stage procedure of suturing a central epidermal graft in place and later reforming the fornices with Esser's procedure. They found that, in sockets with a combination epidermal and mucous membrane lining, there was a period of increased secretion which gradually reduced, with the epidermal graft becoming soft and flexible within a year. They also emphasize the importance of a normal-appearing caruncle for proper cosmetic appearance, and advise that, if it is bound down with scar tissue, it should be freed by means of a "Z" plastic or a mucous membrane graft.

Free mucous membrane grafts have occasionally been advocated for repair of contracted sockets. For women, Clay and Baird[180] advised use of two grafts, each about 3 by 5 cm., taken from each side of the vagina, from between the inner margins of the labia minora and the outer margins of the hymen. In men, they preferred mucous membrane from the prepuce but, if the con-

junctival defect was large, insufficient mucous membrane could be obtained from that site. MacKenzie[181] lists the preferable sites for obtaining donor grafts as follows: in the male, (1) mouth, (2) prepuce; in the female (1) vagina, (2) mouth.

De Roetth[182] employed fetal membranes for repair of conjunctival defects, the chorion surface being placed against the raw surface and the amnion forming the free surface, but found very marked shrinkage after three weeks. Law and Phillip[183] used amnioplastic and noted some shrinkage after three months but retention of a fornix of fair depth.

Berens[184] devised an operation to restore the lower cul-de-sac which preserved the overlying conjunctiva, and thus obviated the necessity of any grafting, for use in those cases where the lower fornix was obliterated by subconjunctival scar tissue but where there was no serious shortage of conjunctiva.

He made a 2-cm. vertical incision into the lower cul-de-sac at the outer canthus. Working through this incision, he undermined the conjunctiva and removed all scar tissue down to and along the entire extent of the anterior surface of the lower orbital margin. He then passed three double-armed silk sutures through the mobilized conjunctiva, into the depths of the reformed cul-de-sac, and out through skin at the orbital margin, tying the sutures over rubber pegs (Snellen sutures). With this procedure, he found it unnecessary to insert any conformer or prothesis at the close of operation.

For reformation of an obliterated lower fornix, Nordlow[154] dissected the conjunctiva from the lower lid and carried his dissection down beneath the orbital margin, shortened the lid with a Kuhnt-Szymanowski operation, and sutured the conjunctiva into the resulting cul-de-sac with Snellen sutures. Weskamp[155] described Damel's technique for restoration of the lower cul-de-sac as incising the conjunctiva horizontally 6 mm. back of the lid margin, undermining the palpebral

conjunctiva, dissecting the lid free to the orbital margin, and suturing the edge of the undermined conjunctiva to the inner surface of the skin of the lid near the orbital margin. The remaining bare surface in the lower portion of the socket is simply allowed to epithelialize over.

Occasionally it is desirable to widen the external canthus. Noyes[186] described the use of a small temporal skin flap for this purpose.

D. DEPRESSED FRACTURE OF ORBITAL FLOOR

Not infrequently, eyes are enucleated because of an injury which is sufficiently severe to fracture the floor of the orbit into the maxillary sinus, with prolapse of orbital structures downward and backward; there is usually an associated comminuted fracture of the zygoma.

If such a fracture is recognized within 2 or 3 weeks of the injury, the proper orbital shape can generally be restored by packing iodoform gauze in the antrum. Later, such a defect is more easily repaired by a subperiosteal implantation along the depressed orbital floor, but the bony orbital floor should be completely healed before an operation of this sort is performed.

For building up the orbital floor fascia lata, cartilage, bone, tantalum, acrylic, and glass wool (fiberglas) have been utilized.[158, 187, 188] Autogenous cartilage or fascia lata grafts have the least chance of resulting in infection, while glass wool or tantalum wool is easier to insert in proper position for correcting the defect.

E. PARTIAL OR COMPLETE EXENTERATION

After exenteration of the orbit the defect is generally best covered by a latex prosthesis or simply an inconspicuous patch. However, a few surgical procedures, none of them very satisfactory, have been advocated for partial cosmetic repair.

Golovine[189] utilized a pedicle skin flap from the temporal region which he carried through a vertical incision behind the outer

canthus and sutured into the orbit along the edges of conjunctiva, the lids having been preserved. After the graft had taken well, the pedicle was cut, the skin incision outside the canthus was closed, and an artificial eye could be retained within the lids.

Goldstein[190] freed the lids, after healing was complete, and lined the undersurface of each lid with Thiersch grafts. He then split the lids and inserted Thiersch grafts, and the patient was able to wear a prosthesis which would fit into these slits.

Hagedoorn[191] described a four-stage operation for use after complete exenteration but with retention of skin of the lids. The first stage was implantation of fat and connective tissue beneath the lining of the lower part of the orbit; the second stage was mobilization of the overlying epithelium and moving the fat back to the apex of the orbit; the third stage was mobilization of the skin of the lids and completing the filling of the orbit by means of another fat transplant; and the fourth stage was an Esser operation for contracted socket.

Kolen[192] described an ingenious method of reconstructing the eyelids by making pockets beneath abdominal skin and lining the insides of the pockets with mucous membrane grafts. Later, slices of cartilage from the ear were grafted between skin and mucous membrane, and finally the ready-made lids and socket were transferred to their final position via pedicles. Filatov[193] also advocated use of this procedure for reconstruction of a completely exenterated orbit, but he had not actually performed such an operation.

(To be continued)

EVALUATION OF NIGHT VISION*

PHILLIP ROBB McDONALD, M.D.

Philadelphia, Pennsylvania

INTRODUCTION

The physiology of rod and cone vision has been under investigation for many years. Schultze[1] was the first to suggest, in 1866, that the retina possesses two types of receptor cells, but it was not until 1895 that the duplicity theory was finally established by von Kries.[2] In brief, this proposed that the cones are concerned chiefly with visual acuity and color discrimination at high intensities of illumination while the rods are responsible for vision at low intensities. Parsons introduced the terms "photopic" for vision at high intensities and "scotopic" for vision at low intensities of illumination.

The phenomenon of retinal adaptation was first measured by Aubert[3] in 1865. During the latter part of the 19th century other investigators, notably Koenig and Ritter[4] and Abney and Festing,[5] were concerned chiefly with the effect of wave length on the threshold of the dark-adapted eye. With the development of more precise physical equipment, this work has been repeated several times, the most accurate measurements being those of Hecht and Williams[6] and Kohlrausch.[7]

Shortly after the original measurements of retinal adaptation,[3] Boll[8] discovered visual purple (1876), and Kühne[9] was successful in extracting it from the retina (1879). It was natural, therefore, to associate it with the visual process. In fact, Parinaud,[10] in 1895, suggested that night blindness was caused by a deficiency in visual purple.

The correlation of the physiologic studies of retinal sensitivity with the photochemistry of the retina is a most fascinating story,[11] the nature of which was gradually revealed by the work of many investigators. Lythgoe and Tansley,[12] in England, and Hecht[13] and Wald,[14] in this country, have been the principal contributors to this problem.

Coincident with the evolution of our knowledge concerning dark adaptation and the chemical nature of the visual process was the interest shown by the nutritionists in the isolation of the vitamins. It had been known for many years that a nutritional deficiency might cause impairment of night vision. Studies on the relationship of vitamin A to visual purple and the isolation of vitamin A from the retina by Wald[14a] provided further impetus to the study of dark adaptation as a measure of vitamin-A deficiency. The literature on this subject has recently been reviewed by Schmidtke.[15] The results varied with the socio-economic status of the group tested, the apparatus used, and the enthusiasm of the reporter. It became apparent that vitamin-A deficiency did raise the light threshold of the dark-adapted eye. However, the subjective nature of the test and the many variables that had to be considered did not permit its acceptance as a routine method for the determination of vitamin-A deficiency.

Numerous instruments have been devised for testing the light sense. Until the advent of our interest in the test as a measure of vitamin-A deficiency, most of these were well-standardized models relegated to the research laboratories of those interested in visual physiology. The popularization of the test, however, led to the development of some instruments that could not fulfill the claims of the manufacturers. The literature on the instruments available prior to World War II has been adequately reviewed by Sloan.[16]

With the onset of the war, it was soon realized that, although great advances had been made in our knowledge of visual capacities at scotopic levels of illumination,

there were still many problems of a practical nature that were left unsolved. The hours from dusk to dawn assumed a new importance. The evaluation of night vision became of paramount interest both from the point of view of identification of enemy aircraft and the operation of aerial attacks against the enemy.

The problem presented to the military services, especially with regard to aviation, can be briefly stated as (1) what variation in the visual threshold might be expected in a highly selected group of individuals, (2) what type of night-vision test suitable for mass testing could best reduplicate the visual tasks required in night operations, (3) providing a satisfactory test were developed what would be its reproducibility and reliability, (4) what would be the validity of the test, (5) what means, if any, could be used to improve the visual threshold of supposedly normal individuals?

The investigative work to be reported here relates to the first, third, and fifth parts of this problem. It will be described in the order in which it was carried out and will be followed by a general discussion of the problem as outlined in the preceding paragraph.

EXPERIMENTAL WORK

OBJECTIVES

1. To determine the variations in certain criteria of dark adaptation in a group of individuals of the same age who had passed the rigid physical examination for aviation cadets and who followed the same dietary regimen.

2. To determine whether large doses of Vitamin A as a supplement to an adequate diet would improve the visual threshold.

3. To study the reproducibility and reliability of two different tests of night vision.

The dark-adaptation tests were conducted on 162 aviation cadets stationed at Randolph Field, Texas, during the summer of 1941. These cadets, selected at random by their officers, were all supposedly in perfect health, with uncorrected visual acuity of 20/20 or better and with no evidence of ocular disease. The examinations were made by me during the second 10-week period of their flying training. The cadets, all of whom lived in permanent barracks, were fed in a central mess hall. The food was excellent and unlimited quantities of milk, butter, eggs, and green vegetables were provided. In accordance with military procedure the cadets were allowed off the post only on Saturday nights; on other nights—except while flying at night—they were in their barracks by nine o'clock.

The examinations were conducted in a photographic darkroom, adequately ventilated to insure comfort. Unless stated otherwise, the dark adaptometer devised by Hecht and Shlaer[17] was used and the procedures recommended by them followed. On calibration of the standard lamp, the logarithm of its intensity in micromicrolamberts ($\mu. \mu. 1$) was 12.962. The right eye of the examinee was used in all experiments, the chin rest being adjusted to the right height by means of a pinhole disc temporarily inserted into the eyepiece of the instrument.

For light adaptation, the right eye was adapted to an intensity of 982 millilamberts for three minutes. The test field was three degrees in angular diameter and fell seven degrees to the nasal side of the macula. A violet filter (Corning 511) was used in the test field which was exposed in flashes of one fifth of a second. The intensity of the testing light was controlled by means of a neutral wedge and filters. This intensity was usually set by means of the wedge below the expected threshold value for the first flash and then was increased by steps of 0.1 (log $\mu. \mu. 1$) until the observer reported seeing a flash.

The rod threshold was determined by the "method of limits" described in the following part of this paper. Dark adaptation was measured over a period of 30 to 35 minutes. Threshold readings were recorded as the logarithms of the intensity expressed in micromicrolamberts (ordinates) and plotted

against time in minutes (abscissa).

Range of dark adaptation threshold. The first factor to be determined was the variation in the range of the dark adaptation threshold in such a group of cadets, whose ages ranged from 19 to 25 years. The entire course of dark adaptation was recorded for all individuals. The criteria selected for study were the cone threshold and final rod threshold. In the entire sample 81.5 percent had final rod threshold values between 2.7 to 3.0 (log μ. μ. 1) and 75.3 percent had cone threshold values between 5.6 and 5.9 (log μ. μ. 1). If the data are analyzed statistically, the logarithm of the mean cone threshold in micromicrolamberts was 5.75 with a standard deviation (δ) of 0.198 logarithmic units. The logarithm of the mean rod threshold in micromicrolamberts was 2.84 with a standard deviation (δ) of 0.156 logarithmic units. The correlation coefficient of the two final thresholds is 0.20. This value is on the border line of statistical significance. The low correlation between these two thresholds had been previously reported by Hecht.[18]

Three categories were arbitrarily chosen to classify performance in the dark adaptation tests. Listed as *good* were all observers whose final rod threshold fell within one standard deviation above or below mean (2.68 to 3.00 log μ. μ. 1); as *excellent,* all those whose thresholds were lower than one standard deviation (2.68 log μ. μ. 1 or less); and as *fair,* those whose thresholds were greater than one standard deviation from the mean (3.00 μ. μ. 1). None of those examined had thresholds high enough to suggest any evidence of night blindness or to warrant their performance being classified as poor. The cone threshold was not considered in this classification.

Vitamin-A effects on night vision. In a study such as this, it is only natural that one of the features to be investigated should be factors that might improve the visual threshold. Of the group of 162 cadets examined in the preliminary survey, the last 40 were detailed for this experiment. When reporting for further night-vision tests, every alternate cadet was used as a control subject. No selection was attempted to include persons with high or low thresholds. The subjects were examined twice before starting the experiment. One group received 50,000 units of vitamin A a day as a supplement to their usual diet, the other group received only the ordinary cadet mess diet. The vitamin A was taken in the presence of an officer immediately following the noonday meal. The entire group was examined weekly for a period of eight weeks.

The total number of examinations in the control group was slightly less (9) than in the vitamin-A group because of examinations unavoidably missed. Half the group was examined in the morning and half in the afternoon, since this fitted their flying schedule. One week each group was seen before exposure to much sunlight and the following week was seen after 1 to 2 hours of flying. This balanced the rise in threshold that might occur following exposure to bright sunlight for a period of several hours.[19]

The statistical analysis is based on 38 individuals since two "washed out" before the experiment was completed. The results are listed together in Table 1. In order to appreciate fully the improvement that may take place as familiarity with the test increases, the data have been further broken down so that one can compare the mean thresholds of the first two and last two examinations.

In the group receiving vitamin A, the drug was not started until after the second examination. Those receiving vitamin A showed an improvement in their mean cone thresholds of 0.158 logarithmic units while the control group improved by 0.108 logarithmic units. The difference (Δ) 0.050 between these two values is not significant statistically since it is less than twice the standard error of 0.051.

Similarly the improvement in the mean rod threshold of those receiving vitamin A was

0.150 logarithmic units while the control group showed an improvement of 0.108 logarithmic units. The difference (Δ) 0.042 between these two values is also less than twice the standard error of 0.050, again not

it was found (in the control group) that there was no significant improvement in the mean cone or rod threshold after the first two tests. One might expect slight improvement with practice but this was to all intents

TABLE 1

statistically significant. The improvement in the control group can be ascribed only to the "learning" factor which is a common observation in subjective tests of this nature.

Reliability and reproducibility of night-vision tests. In any test of night vision, it is essential that the test be reliable and that the results be reproducible. In the experiment reported (*Vitamin-A effects on night vision*)

and purposes negligible after the second test.

The fact that one particular test of night vision is reproducible and reliable does not necessarily mean that all other tests of a similar nature will have the same reliability. Even if another test proves to measure reliably the functions it purports to measure, there may be a poor correlation between the two tests. This is especially true if the two

tests are measuring visual functions at different levels of illumniation.

To evaluate the reliablity and reproducibility of a night-vision test using form discrimination, 85 cadets were examined by at a level high enough so that all presentations should be seen readily and finishing at a level at which, in most instances, none could be seen. The test therefore has yielded a score between 0 and 40.

another test using the method of "frequency of seeing" [43b] described later. This required the recognition of a Landolt C subtending a visual angle of two degrees. The test object was automatically presented five times at eight different levels of illumination, starting

The test was carefully explained to the cadets and, after thorough dark adaptation, the value of parafoveal vision was demonstrated by means of a preview of the test. Table 2 lists the scores on the four tests. It must be pointed out that the first and second

tests were given on the same day and the third and fourth approximately one week later.

The statistical analysis of the data is presented in Table 3. This shows that the practice effect is greatest between the first and second tests, the mean difference between the scores being less than 3.72. Subsequent retests are of little value. The mean difference between the scores on the second and fourth totals is 0.68. The relation between the second and fourth tests can be seen in Figure 1. The correlation between these two tests is 0.797, which is very good. Again this shows that after the second test there is little subjective improvement in a test of this nature.

DISCUSSION

Before adopting any test of night vision, it is essential to know what variation might

TABLE 3

be expected in the population to be tested. Several surveys of fairly large numbers of supposedly normal individuals have been published. The results have varied somewhat,
Fig. 1 (McDonald). The scores of the second and fourth tests on the A.A.F. night-vision tester, plotted together to show the correlation between the two tests.

depending upon the type of instrument employed. The one used in this survey was the same as that used by Hecht and Mandelbaum[18] in their study of 110 university people. Solandt and Best[20] used a later modification of the same instrument, while Yudkin and Robertson[21] used one embodying the same general principles. The results of these surveys are in close agreement. Bishop Harman,[22] Rycroft[23] and Lister,[24] in England, have also reported on large groups of individuals. Their respective instruments required the recognition of a form at a low level of illumination. Their data, though significant, are hardly comparable, since the results are not expressed in units of brightness or illumination.

The Hecht instruments measure the threshold with a well-controlled patch of light. As Godding[25] has pointed out, however, there is a difference between the measurement of the absolute threshold and the recognition of various forms or letters at low intensities of illumination. This fact alone may account for the apparent differences in the results that have arisen in the various studies of night vision. This will be amplified in the discussion of the various instruments that recently have been developed.

At the time my experimental work was done, the only available material was that of Hecht and Mandelbaum.[18] The data on both these groups were compiled on the results of the individual's first performance of such a test. The results show striking similarity. As might be expected in a group of younger individuals, the final rod threshold is slightly lower, although the cadet group was essentially the same as the 21-to-25-year age group reported by Hecht and Mandelbaum.[18] Since the cadets were a highly selected and physically homogenous group, all eating the same food and living under the same conditions, a greater difference might have been expected between these two groups.

The spread of the final rod threshold was approximately one log unit which is also the same as reported by others.[18, 21] This means that the threshold of the poorest individual was 10 times higher than that of the best. When one considers that the total threshold change is at least four log units, or 10,000 to 1, this variation is comparatively small. One may expect therefore that the visual threshold may vary by a factor of 10 in a group of aviation cadets.

The study of visual perception under conditions of threshold illumination has not been evaluated without some difference in opinion attested to by the several instruments that have been developed to measure this function. Each one has had certain purported advantages such as ease of administration, rapidity and simplicity of the test, and so on. Hecht,[18] Craik[26] and Tansley[27] have repeatedly emphasized that the fundamental physiologic principles must be fully appreciated and followed to insure reliable measurements and the basic criteria for a satisfactory test of dark adaptation have been fully discussed by them. Briefly the factors to be considered are: 1. Time and intensity of the preadapting light; 2. location of the retinal area tested; 3. size of the retinal area stimulated; 4. time of exposure of the test flash; 5. wave length of the testing light.

These criteria must be followed to devise an accurate test of some basic visual function at low levels of illumination such as the measure of the absolute threshold to a flash of light, or of some simple visual task such as the recognition of the direction of an arrow, at any given low level of illumination. The advantages of such a test are that in measuring one visual function over a fairly narrow range of illumination, the test would be fairly simple to give and might readily lend itself to mass testing. Another argument in favor of a simple test of threshold or visual acuity at low levels of illumination is based on Shlaer's[28] studies, which showed that visual acuity at such levels varies as the logarithm of the intensity; therefore, such a test might give sufficient

information as to visual acuity at higher levels of scotopic vision.

Additionally, the requirements for a test of night vision peculiar to the needs of the military services demanded that it reproduce as closely as possible the visual discrimination encountered in night operations.

The most difficult task was to define what visual discriminations might be encountered in night operations. These may vary from determination of the absolute threshold to the recognition of forms of varying size and contrast, from low levels of illumination to the wide ranges of sky brightness found in starlit or moonlit nights. It is obvious that no one test could fulfill this range of requirements. However, one could aim at a test of form discrimination at intensities well within the range of scotopic vision. A test which approximates these conditions has been called by Livingston[29] "a test of night visual capacity," a term that would seem more appropriate to denote the visual discriminations required.

Such a test would have the advantage of approaching more closely to actual operating conditions and by so doing should make performance on the test correlate better with actual practice. One of the disadvantages is that it must needs be a compromise, since it would not be feasible to measure any one visual function over the wide range of intensities encountered in night operations.

Another disadvantage is that extraneous factors would be introduced that would have no real bearing on the visual task to be measured. Craik[26b] and Godding[25a] have clearly shown that the perception of a silhouette or other more complicated material is not a test of dark adaptation. Consideration must be given to visual, adaptive, psychologic, and training factors in any such test. True, good dark adaptation is a requirement for a high standard of night visual capacity but, as Craik[25b] has shown, there is little correlation between such tests and the absolute threshold of rod vision.

These objections, however, were outweighed by the desire to produce a test that would more closely approximate the visual discriminations encountered in night operations. How best could this be done without disregarding the basic fundamentals for a satisfactory test of dark adaptation?

The first point to be considered was the necessity of *preadapting the eye* or eyes to a light of unknown intensity for a fixed interval of time. The purpose of preadapting the eyes to a bright light is to bleach the visual purple in the retina with a known quantity of light. This enables one to measure the course of dark adaptation from a known standard level and permits comparable measurements which are independent of the level of the environmental illumination. This difference in rate of adaptation is clearly demonstrated on entering a darkened theatre on a bright, sunny day or during a dimout.

If one is not particularly concerned with the course of dark adaptation, a common level of dark adaptation can be obtained by keeping the subjects in a darkroom for a minimum of 30 minutes, after which there is, for most practical purposes, little change in the rod threshold. An important consideration here is that, in measuring thresholds during the course of dark adaptation, the final rod threshold has been found to be the most reliable measurement.[21, 25a, 30, 31]

Another argument against the measurement of the rate or course of dark adaptation is the time factor—numerous determinations would have to be made and the value of this information in contrast to a few more accurate measurements at the desired levels of illumination is questionable. (This was evident in the measurements of the complete course of dark adaptation on the 162 cadets in the experiments reported above.)

Because of these factors and because of a desire to measure visual efficiency at various levels of low illumination rather than the rate of adaptation or a threshold at one fixed

level, it can be assumed that, for the purposes of the military services, preadaptation could be dispensed with and an equal retinal level could best be reached by a carefully regulated period in which all subjects were kept in darkness.

This is the procedure that has been followed in most of the night-vision tests used by the various armed services. The wearing of red goggles[32, 33] transmitting light only beyond 620 μ can considerably reduce the time to be spent in actual darkness. The effectiveness of the goggles depends upon their cutting down the total amount of light transmitted and upon the difference in the stimulating power of white and red light on the rods.[34]

The *location of the retinal area* to be tested can be determined by the use of some fixation device.[35] If binocular vision is used, corresponding areas of retina will be stimulated. Hecht[17, 18] has emphasized that the control of fixation gives greater accuracy to the test since a predetermined area of the parafoveal retina is stimulated. Godding,[25a, b] however, feels that if a larger test field is used, that is, one subtending a visual angle of seven degrees, fixation devices can be dispensed with.

The use of a fixation device would not be in keeping with the desire to reproduce as closely as possible the actual conditions encountered in night operations. It must also be borne in mind that the region of the retina having the maximum scotopic acuity may vary from individual to individual and an alert examinee may do better if he is not required to fixate.

All pilots and gunners are taught to scan and to use a roving gaze, although through force of habit the tendency is to fixate an object to see it clearly. Hence, an examinee who did not use his parafoveal vision although instructed to do so might fail the test, in which case his unsatisfactory night vision would be due to inattention and not to a defect in his visual apparatus.

Nevertheless, even though some individuals may be penalized, the advantages of permitting free movement of the eyes is believed to outweight the use of a fixation point. This is especially true if the examinees are given a practice test to demonstrate to themselves that in the dark-adapted state "off center vision" is better than direct vision. This can serve as a graphic proof of the increased sensitivity of the parafoveal retina.

The total *area of retina stimulated* necessarily depends to some extent on the nature of the test. In determining the visual threshold to a flash of light, Hecht[17, 18] advocated that the testing light subtend a visual angle of at least two degrees, this being large enough to give a uniform cross section of the retina. It was assumed, of course, that a fixation device would be employed. Godding[25a, b] favored using a seven-degree field without fixation, since threshold brightness is independent of area considerations in a test field of that size. However, if one is to measure visual *acuity* at scotopic levels of illumination, the size of the test object used will depend upon the level of illumination at which the test is to be conducted. This can be understood best by reference to Figure 2 which is adapted from some unpublished data (Hartline and McDonald).

Since visual acuity is dependent upon illumination,[28] a larger test object must be used if one is to test visual acuity at levels of illumination below that of a starlight night than if one were to test it at brightness levels between those of starlit and moonlit nights; conversely, a decrease in the size of the test object must necessarily be accompanied by an increase in the general level of illumination.

Thus, if a test letter subtending a visual angle of two degrees is used, it should be exposed on a test field subtending a visual angle of four degrees; otherwise the character will tend to fill up the field and clues other than visual acuity will come into play, that is, if a letter T subtending a visual angle of two degrees were exposed on a 3-degree

field, one could tell the position of the T by determining the darker side of the field; exposed on a 4-degree field this clue would be eliminated. Therefore, in a test of visual acuity, the area of retina stimulated will depend on the criteria established for the general level of illumination at which the test is to be conducted.

The *time of exposure of the test object* also depends on the nature of the test.

tion at low levels of illumination. Minor variations in the brightness of the light source at photopic levels are not of great importance, but in the measurement of the threshold of vision at scotopic levels such variations become of much greater significance. Hence, it must be insured that the light source is not subject to variations in intensity. This should be controlled by neutral density filters and not by varying the
Fig. 2 (McDonald). A composite graph to show the relationship between visual acuity and illumination. The approximate brightness of the starlight and moonlight skies is also recorded. The size of the letter and visual acuity are plotted against the intensity which is recorded as the logarithm of the intensity expressed in micromicrolamberts and also in microlamberts.

Hecht[17, 18] advocated that, in the determination of flash thresholds, the duration of the flash be one-fifth second, since this is long enough to be well within the physiologic limits of the retinal reaction time. When a test object without a fixation spot is being used, longer exposures are necessary to obtain threshold readings.[25a, b] At low levels of illumination, exposure should be long enough for the examinee to be able to shift his gaze or try several areas of his parafoveal retina and yet not be long enough to induce fatigue. An exposure of 5 to 10 seconds should amply fulfill this requirement.

The source of *light* is one of the most important features of any test of visual func-

brightness of the light. The latter method would cause variations in the color temperature of the test light which in turn would give rise to the Purkinje phenomenon and affect the results of the test.

In order to produce maximum stimulation of the rods a blue filter (480 μ.) of constant density should be used in the path of the test light. This wave length produces maximum stimulation of the rods and also approximates the spectral characteristics of the night sky more closely than white light. The use of white light, however, would be quite satisfactory provided the same means of controlling the intensity were used.

Of the criteria mentioned for a satisfac-

tory test of dark adaptation, one can therefore omit a period of light adaptation, since the rate of adaptation is not under consideration and for practical purposes a period of 30 minutes' dark adaptation will insure a standard level for all examinees. Likewise, in an attempt to simulate operative conditions, the use of a fixation point to insure testing the same retinal area in all individuals can be omitted. A test of night visual capacity, therefore, resolves itself into a test of form discrimination at whatever level of illumination will most nearly approximate conditions under which night missions are performed.

The exact duplication of the specific conditions of night operations would require a fairly complicated test with many variables. Some compromise must, therefore, be made between comprehensiveness and practicability. Actually the visual task varies from the use of the threshold of vision to the discrimination of various size forms of varying contrast over the range of illumination of the night sky. The upper limits of these visual discriminations would necessarily involve some measurement of photopic acuity—such levels being reached on a moonlit night.

Since it is desired to measure scotopic acuity only, the level of illumination should therefore be restricted to that no higher than the starlit sky. At this level, however, one could devise a test in which the test object would vary in size and contrast (black to gray) and be presented on a white background, the brightness of which was kept within the desired limits. Such a test involves three variables and the more variables introduced the more difficult is the test to control. Wright[36] has devised a test of this nature. A series of Landolt C's, varying in brightness from white to gray, are exposed on a black background. The source of illumination is a plaque of luminous radium compound placed to one side of the test plate.

A simpler test would be to have either a test object of fairly large size and constant contrast which is viewed at varying levels of illumination well within the scotopic range, or to have test objects of varying size viewed at a fixed level of illumination also within the scotopic range. Measurements of dark adaptation[18, 21, 37] have shown that rod or scotopic vision covers a range of illumination of approximately 2.5 log $\mu.\mu.$ 1 (flash threshold) to 5.5 log $\mu.\mu.$ 1.

Reference to Figure 2 shows that a Landolt C subtending a visual angle of four degrees (visual acuity 20/1000) can be seen at a level of illumination of approximately four log $\mu.\mu.$ 1, whereas a similar letter subtending a visual angle of one degree (20/250) requires a level of illumination of approximately 5.2 log $\mu.\mu.$ 1.

The recognition of the letters T or E subtending the same visual angle could be accomplished at lower levels of illumination since the visual task is somewhat easier. However, no matter what is used as a test object—airplane silhouette, boat, or other symbol—the correct visual angle can be determined if the levels of illumination at which it is desired to conduct the test are decided upon.

To recognize a test object subtending a visual angle of one degree or less requires a level of illumination at the borderline of scotopic and photopic vision. Many night operations are carried out at sky brightnesses varying between starlight and moonlight, but such a test is not one of rod vision. At these relatively higher levels of illumination, it is difficult to determine exactly what one is measuring. Visual tests below this level of illumination correlate fairly well with each other as do tests which involve predominantly cone vision. Tests which involve both rod and cone vision show very poor intercorrelation with tests of either rod or cone vision.

TEST INSTRUMENTS

Most of the instruments described since 1939 embody some but not all of the criteria which have been described above; they all differ to some extent. Haines[38,] described a simple instrument which provides for a

period of light adaptation after which the time taken to recognize the position of an arrow at some predetermined low level of illumination is recorded. As many readings as desired can be taken by resetting the intensity and one can therefore measure the change in threshold over a period of time. Yudkin[39] made some further improvements in the same instrument and used it for threshold measurements of a spot of light rather than of the recognition of an arrow.

Bishop Harman[22a, b] has described a simple test in which the examinee is required to recognize the number of discs on a black screen. There are four groups of discs, the number of discs varying in each group. The light source is a standard candle set at a predetermined distance. The examinee approaches the test screen until he answers correctly. This test has met with considerable criticism.[40]

The two most widely used tests in England during the war were those designed by Craik and by Livingston.[29a, b] The Craik test, described by Rycroft,[23] was known as the Pentagon test and was used by the British Army. It consisted essentially of a five-sided figure on each face of which was a letter V in different positions. The light source was within the instrument but the sides were so arranged that the intensity was different on each face. The candidate was scored on a basis of 5/5, 4/5, and so on.

The rotating hexagon described by Livingston[29a, b] was a much more elaborate instrument, designed to test six individuals simultaneously. On each face of the instrument there are 16 figures, crosses, silhouettes, letters, and so on. The test figures are exposed at different levels of illumination and the candidate scored on a basis of the number correct out of the 32 presentations. The figures are stated to subtend the same visual angle though they vary rather markedly in difficulty of recognition. Because of the mechanical nature of the test there are many places where errors could arise

such as variations of intensity from panel to panel, from instrument to instrument, and so on. However, the principal criticism of the test is that raised by Godding[25a, b]: it is not a test of dark adaptation. Livingston designed it, however, as a test to determine night visual capacity, and even though other visual, psychologic, and training factors had to be considered, it probably served its purpose.

Both of these tests were concerned with measuring visual acuity at low levels of illumination. The size of the test object was kept constant but the illumination was varied. The only objection that might be raised is that the range of intensity, especially in the Craik test, was not broad enough to permit an adequate quantitative evaluation of the results.

Godding[25a] and Koch[30a, b] have also described instruments for testing the light sense. Both of these adhere strictly to the essential criteria for a satisfactory instrument. The Koch instrument was used by Michaelson[41] in testing army personnel and, contrary to the statements of most other military personnel, he believes that an instrument determining the minimum light threshold is of more value than one determining the minimum form threshold.

The Canadian Army and Air Force used some of the instruments designed by the English though they were chiefly concerned with night-vision training.[42] At the end of the training period the examinees were required to spot the direction of a black disc on a contrasting background, that is, was it vertical, right or left? The relative merits of night-vision training and night-vision testing are not pertinent to this discussion. The Canadian Navy[20] used a modification of the Hecht-Shlaer instrument. The only essential change was to make the instrument more compact and to permit binocular viewing of the test field. In their hands, this instrument proved satisfactory.

In this country there was just as much

diversity of opinion about the best instrument as elsewhere. The Army Air Corps had four different types of instruments to test night vision.[43a, b, c] The large instrument mentioned in the first part of this paper was designed to test large numbers of individuals at training centers, and to be as free of human error as possible. The test object was automatically presented five times at eight different levels of illumination in 1 of 8 positions. The exposure time of 10 seconds and the change in illumination were all automatically controlled. Six examinees were tested at one time. Each had in front of him a model of the test object, a letter C made out of plastic. They were required to turn the break in the C to correspond with that of the test object; the response was automatically recorded if correct. Although the more complicated the mechanical device the greater the chance for mechanical failure, the instrument definitely fulfilled a purpose.

The other three types of instruments available were of the so-called portable variety: the Hecht-Shlaer instrument as designed for the Canadian Navy and the night-vision testers of the School of Aviation Medicine, and the Aero Medical Laboratory.[43a, c] The School of Aviation Medicine night-vision tester required the recognition of a Landolt C subtending a visual angle of two degrees. The source of illumination was a plaque of self-luminous paint behind the test letter, the intensity being controlled with neutral density filters. The test was conducted at 12 inches. The Aero Medical Laboratory's night-vision tester was similar in principle. The source of illumination was radium salt in a moisture-proof cell. The test letter was also a Landolt C. The candidate was first tested at 11 feet from the instrument; if he did not get 4 out of 5 presentations he was moved up to 9, 7, or 5 feet. The results were recorded as the distance at which the examinee got 4 out of 5 presentations correctly.

The United States Navy[44] employed a test somewhat similar to the Aero Medical Laboratory's test. The source of illumination was a radium plaque. In front of it was the test letter. A fixation device was attached to the side of the instrument.

Thus the instruments in general use by the Armed Services had one thing in common, that is, the recognition of a form at a low level of illumination. Some of the silhouettes, as in Livingston's[29] instrument, were rather complicated and the criticism that this was not a test of dark adaptation would appear justified. In this country, a test of much simpler form discrimination was employed. The size of the letter was determined by experiment to be one which would test scotopic acuity below the level of a starlit night (fig. 2).

Probably the most important feature of any such test is the control of illumination of the test object. This can be either a light bulb or a luminous plaque of a radium compound. Both have advantages and certain disadvantages. A properly controlled light source with provisions to check its brightness periodically is probably the better of the two. Trained personnel and adequate equipment are needed to do this properly. The radium plaques have the disadvantages of deteriorating slightly in intensity and of being affected by exposure to light. However, if the proper precautions are taken, they prove to be quite satisfactory in the smaller types of instruments. They have the distinct advantage of not requiring elaborate devices to ensure constant brightness.

TEST SCORING

No matter how accurate or elaborate a test one may devise, the entire value of the test may be nullified by improper scoring. Unfortunately, many investigators have not paid sufficient attention to this aspect. Thus, in the routine laboratory or clinical tests of dark adaptation the usual method of determining the threshold is by the "method of limits," that is, starting with flashes that can-

not be seen, the intensity of the test light is increased in small fixed steps until a flash is reported as seen, the intensity is then reduced about 0.2 μ. μ. 1 and after a brief pause the flash is repeated. After 3 or 4 flashes two values are arrived at—one where the flash is seen and one where it is not. If there is not too great a difference between the two values, the intensity at which 2 out of 3 flashes are seen is called the threshold. This method is not too laborious and was employed by Solandt and Best[20] in testing a large group.

A more accurate method of determining threshold is by "frequency-of-seeing curve" (unpublished data, Hartline and McDonald). Knowing the approximate threshold, a specified number of flashes are given in random order at each of several intensities, approximately 0.10 log μ. μ. 1 apart. At the highest intensity the flashes should be seen on every presentation, and at the lowest, none; at the intermediate intensities, some are seen and others are not. The mean threshold is therefore somewhere between these intensities, theoretically at that intensity where one half the flashes are seen and one half are not.

The number of correct responses may be used to determine the actual mean threshold or they may be used as a score to differentiate individuals. If an individual sees 25 out of 40 presentations, he is obviously better than anyone who sees only 15 out of 40. (This method of measuring stimuli is fairly commonly used in psychophysical methods of measuring sensation.) It has one distinct advantage in that it lends itself to scoring a routine or semiautomatic test. This is the method employed with the American Army Air Force Night-Vision Tester.[43b] It would appear laborious for a manually operated test but actually it would not be if the test were set up correctly. In an instrument allowing four different positions of the test letter, the test object could be presented 12 or 16 times at 3 or 4 levels of illumination. The score of number correct would be easier to tabulate and would be more accurate than just reading the intensity or the distance at which 4 out of 5 presentations were called correctly. If a candidate did that on his first trial the tendency would be to record that as his score and not make any further examination.

It must be remembered that in any subjective test of this nature, there are many factors to be considered apart from the instrument. For many this test is an entirely new experience. In a desire to do well, some may forget to use the parafoveal retina. Others, trying to avoid certain types of duty, may deliberately fail the test.

One must also consider the individual giving the test. Hour after hour in a dark, poorly ventilated room may soon dampen his enthusiasm and result in carelessness and inattention. These and other intangible factors must all be evaluated.

RELIABILITY AND VALIDITY

Finally, in any test of visual function, it is important to know the reliability and validity of the test. As is to be expected, there was little opportunity to investigate this problem in time of stress. To say a test is reliable means that it must align individuals about the same way each time the test is given. This in turn depends primarily upon (1) the accuracy and standardization of the instrument, technique, procedure, and so on, and (2) the size of the intraindividual variation as compared with the interindividual variation in the population tested.

It has been shown in the group of 162 cadets that there is an interindividual variation of the visual threshold of one log unit. If each individual were to show a day-to-day variation of one log unit (intraindividual variation), the test could not be considered reliable since it could not align individuals in the same way at each test. This would not be a criticism of the instrument, but, in statistical terms, the test would not be reliable since in the visual function tested each individual

might vary as much as the whole group.

The two different tests of dark adaptation in this report show good test-retest reliability. The correlation between the two tests has not been made because these studies were carried out at different times and on different individuals. Since most of the different instruments described above were modified from instruments known to have good reliability, the authors have for the most part not retested large groups of individuals. Yudkin, and others,[21] reported that on retests of the same individual the final rod threshold varied by about 0.2 log units. This is in close agreement with my findings and those of Hecht and Mandelbaum.[18]

The validity of the test is the correlation of the results of the test with some measure of performance, that is, flying ability (accident rate, success or failure in flying training, enemy planes shot down at night, and so on). The validity will be low (1) if the function tested has little or no correlation with the test of flying, (2) if the test is not reliable due either to poor technique and instrumentation or to little difference in the intraindividual variation as compared to the interindividual variation, or (3) if the test scores do not have a high correlation with the critical function purportedly measured.

Unfortunately, there has been no validation of these tests against actual performance. This is true for most of our tests of visual function. In fact most of our physical standards have been established without any validation. Moreover, any one function we measure contributes such a small part to the actual performance of flying that its validation is extremely difficult.

Most of the studies on dark adaptation within the past few years have been concerned with factors that impair night vision. The role of vitamin A deficiency in causing impairment of night vision is now well established and it is well recognized that the response to vitamin A therapy varies from individual to individual.[14 6, 15, 18, 21] It has also

been clearly shown[45] that there are various ocular conditions that may account for an abnormal rise in the visual threshold, and that there are also certain other physiologic factors that may cause such a rise. One of these is the deterioration of night vision with age[46, 47] which has been attributed to a decrease in the pupillary diameter. Anoxia has also been shown[48-51] to cause such a rise. This is believed to be brought about by the effect of anoxia on the central nervous system and not on the visual purple.

In any study of night vision, it would seem logical that an attempt be made to improve the visual threshold of normal individuals. Anything that might improve the transparency of the ocular media or increase the concentration of visual purple in the outer limits of the rods should improve night vision. Since there is no known means of improving the transparency of the ocular media, the first obvious approach was to attempt to improve the threshold by feeding large amounts of vitamin A in the hope that this might be reflected in an increase of this protein in the visual purple. In the experiment that was conducted there was no significant improvement in the visual threshold following eight weeks of vitamin-A therapy. This might be expected since the individuals in this age group were in perfect health and their threshold of vision approximated the absolute limit.[131]

Yudkin[52] has reported on the effect of vitamin A, alcohol ,and benzedrine on the final rod threshold. Most of his subjects, however, had thresholds that were considered abnormal. He found that 100,000 units of vitamin A caused an improvement in the threshold within 4 to 10 hours but by 24 hours the threshold had returned to its previous level. Alcohol and benzedrine both caused a transitory improvement of the threshold for 30 to 60 minutes but the effect was not noticeable after 90 minutes. Kekcheev,[53] in a paper that is poorly documented, states that caffeine, kola, and alcohol im-

prove night vision. He also states that stimulation of one sense organ increases the sensitivity of the other sense organs. Listed are stimulants to taste and smell that will improve night vision. In general he believes that pleasant sensations lower the threshold and unpleasant sensations raise the threshold. There is no other literature available to corroborate his claims.

Lythgoe[54] and Craik,[55] in papers that appear to be frequently overlooked, stress the fact that the mechanism of dark adaptation cannot be explained solely on the basis of the bleaching and regeneration of visual purple. Lythgoe believes that the increase in retinal sensitivity to light is brought about by both the regeneration of visual purple and some change in the neural mechanism of the retina. Since Yudkin[52] does not think that the effect of alcohol and benzedrine is brought about by a change in the vitamin-A content of the blood it is possible that these drugs may affect the neural component as proposed by Lythgoe.[54]

The search for some method to improve the visual threshold in normal individuals has not been very productive. In evaluating the effect of substances that affect the entire nervous system, that is, alcohol, anoxia, and so on, great caution must be paid to be certain that the results are accurate.

In some unreported experiments (Hartline and McDonald) on the effect of choline on the visual threshold it was found that in some instances trained individuals reported seeing many more blanks than usual. This might not have been noted except for the fact that the threshold was being measured by the frequency-of-seeing method and it was customary to give each individual a certain number of blank presentations. Unless this had been detected, it is quite probable that the true effect of the drug would have been missed.

CONCLUSIONS

Prior to World War II most of the investigative work on night vision was concerned with physiologic studies of the mechanism of vision or the effect of nutritional deficiencies on the visual process. This work fortunately provided the basic information needed for the tremendous problem of trying to evaluate and protect the night vision of those civilians and soldiers who were required to perform their various duties at night.

Since all physical examinations prior to the war were concerned only with tests at photopic levels of illumination, satisfactory tests at scotopic levels had to be devised. Of necessity some tests were devised and put into operation without much preliminary evaluation. Some sacrificed accuracy for simplicity though, for the most part, the tests were able to detect those who showed defective night vision. Practically all the tests developed during the war had one thing in common: they measured the threshold for form rather than that for light.

The introduction of a measure of visual acuity even at scotopic levels of illumination complicated the test. The criticism that such a test was not a test of scotopic vision was justified especially if the test objects were difficult to recognize or if they were so small (fig. 2) that to be recognized the level of illumination approached that of photopic vision. Most of the tests, especially the more elaborate ones, attempted to assess the examinees' night vision on a quantitative basis.

In the experiments that have been reported the tenfold variation in the final rod threshold of healthy young adults confirms the findings of other investigators. The two different night-vision tests employed, one a test of the visual threshold to a flash of light and the other the recognition of a 2-degree C, have both shown good reproducibility or test-retest reliability. It has also been shown that the visual threshold in normal individuals is not improved with large doses of vitamin A.

In discussing the improvement of the visual threshold, no mention was made of the various means used to protect the thres-

hold, that is, the use of goggles, red lights, developments in instrument panel illumination, the use of oxygen at night, and so on. These do not enter into a discussion of the evaluation of night vision.

The ideal of any test of night vision is that from the results one could eliminate the poor and select the best for special assignments that might involve night operations, and so on. As is frequently the case, the ideal is seldom achieved. If failure on the test means removal of the trainees from certain types of training, especially if such training is none too desirable, the elimination rates goes up once that fact becomes known. In subjective tests of this nature it is very easy to fool the examiner. Given sufficient retests and individual examination the true situation can frequently be uncovered but the excuse can always be given that the test was not understood.

As a means of selecting the best individuals for a particular job, the test is again none too satisfactory when employed on a large scale. There are so many other factors such as motivation, intellect, natural skill with a particular instrument or airplane, and others, that the performance score on a night-vision test is frequently overshadowed by other considerations.

Most of the individuals who complained of difficulty in performing their assigned duties at night were found to have normal night vision. (Such complaints are frequently the earliest manifestation of anxiety.) Despite this, however, it is believed that a test of night vision on all military personnel is worth while—some cases of night blindness are always discovered on routine examinations, especially in groups less highly selected than cadets. Also in the vast majority of individuals this test proves to be the first demonstration they have ever had that, at low levels of illumination, eccentric vision is many times better than central vision.

Like many tests of physical capacity it is no better than the person doing the testing. Given a satisfactory instrument and an interested examiner, a test of night vision becomes an important diagnostic aid as well as a means of demonstrating the important aspects of scotopic vision. However, until this one aspect of visual function is correlated with actual performance, no opinion can be expressed as to its value in a battery of tests for selection of individuals for flying duties.

RIBOFLAVIN TREATMENT OF SPRING CATARRH

H. J. Stern, M.D.
Utica, New York

In 1944, Castellanos[1] published a paper on his experiences with riboflavin in the treatment of spring catarrh (vernal conjunctivitis). He found that 92 percent of 105 patients improved within a short time (35.7 percent in 3 to 4 days and 65 percent in 10 to 15 days) when 1 to 3 mg. of riboflavin were given daily by mouth. During this treatment, the patients also received eyedrops containing adrenalin. He explained this favorable effect by assuming that riboflavin is rapidly destroyed in summer by the increased ultraviolet radiation, and concluded that spring catarrh is actually a riboflavin deficiency.

In a reply in the same journal, Lehrfeld[2] attacks this paper vigorously, denying that riboflavin can conceivably be of any use in the treatment of spring catarrh because this disease has been proved to be of allergic origin. Lehrfeld assumes that the improvement observed by Castellanos in his cases is solely due to the local treatment with adrenalin.

To treat patients with spring catarrh by administering a substance well known to give considerable relief in this condition while experimenting with a new therapeutic agent must be regarded as an inconclusive experimental set-up, and to claim full credit for riboflavin without considering that adrenalin might have had a share in the successful treatment is not justifiable. Moreover, the explanation offered by Castellano was not convincing. Riboflavin deficiency is

a reasonably well-defined clinical picture, and to ascribe a condition to a lack of riboflavin because this substance gives relief can hardly be defended. Moreover, it seems that riboflavin is present in the cornea in its coenzymatic form which is light-stable.[3-5]

However, in view of recent observations on the antiallergic properties of several members of the vitamin-B complex, the idea of testing them on cases of spring catarrh seemed attractive, and the results of this investigation are to a certain degree a vindication of Castellano.

INVESTIGATION

Twenty-two cases of spring catarrh were treated. Of these, 13 presented the palpebral form of the disease, four of them showing only milky conjunctival edema while nine suffered from papillary hypertrophy giving the conjunctiva the typical cobblestone appearance.

Seven cases showed the bulbar form with hyperemia and edema of the bulbar conjunctiva and grayish gelatinous "epaulettes" encroaching upon the cornea to a varying degree. Two cases belonged to the so-called mixed form with involvement of the bulbar as well as the palpebral conjunctiva. In all cases, the history and subjective complaints were typical for the disease.

RESULTS

The nine cases suffering from the palpebral form with papillary hypertrophy re-

ceived 5 mg. of riboflavin twice daily, three of them together with 25 mg. nicotinamide. They responded uniformly well. No other treatment was given during this time.

After the first few days, the subjective symptoms—burning, itching, and photophobia—improved considerably, and the pathologic changes of the palpebral conjunctiva receded to a varying degree, leaving the conjunctiva less hyperemic and smoother. The cobblestones were less marked, although they never disappeared altogether.

The improvement was not maintained when the treatment was discontinued. Riboflavin could be replaced by preparations containing the whole B complex (Betotal, Bevitex, yeast tablets) with satisfactory results, and the combination of riboflavin (5 mg.) and nicotinamide (25 mg.) twice daily seemed particularly effective.

The four cases of palpebral spring catarrh, without papillary hypertrophy but with milky edema only failed to derive any benefit from treatment with riboflavin by mouth or injections of the B complex.

One of the two cases with the mixed form improved somewhat with 3 gm. of yeast tablets daily, the second one did not respond to riboflavin, B complex, nor nicotinamide by mouth.

The same negative results were recorded in the seven cases with the bulbar form of spring catarrh.

DISCUSSION

It is interesting, but cannot be explained at present, why the patients with the bulbar and mild palpebral form of spring catarrh failed to improve under a therapy which proved so beneficial to the cases with papillary hypertrophy (cobble-stones) of the palpebral conjunctiva. Further investigations will have to be made, and it is anticipated that some ideas may be derived from the results as to the peculiar fact that one and the same disease can produce so fundamentally different clinical pictures—if it really is one and the same disease.

An attempt will be made, however, to explain the results obtained in the light of recent knowledge of the antihistamine properties of riboflavin and nicotinamide, by assuming that it is a histamine sensitivity which constitutes the physiopathologic basis of the nosologic entity in the cases deriving benefit from the treatment described.

There can hardly be any doubt that spring catarrh is an allergic condition. Berens[6] and Gifford[7] are the exponents of a small number of authors who doubt this and do not admit allergy as the cause of it in every case. It seems, however, undeniable that a large amount of evidence points to the allergic nature of spring catarrh. The clinical picture with its recurrences; the climatic and seasonal incidence; the frequent association with other allergic conditions as asthma and hay fever; the absence of bacterial agents or inclusion bodies and the presence of eosinophilia; the frequent finding of a positive Prausnitz-Küstner reaction to specific allergens; the reaction of the conjunctiva to adrenalin—all these facts are, according to Lagrange and Delthil,[8] proof of the allergic nature of the condition.

The physiopathologic basis for allergic manifestations is an abnormal response of the capillary system to physical stimuli which causes a disturbance in the capillary circulation. This results in disorders of the cell nutrition, liberation of histamine in the tissue, and disturbances of the fluid and electrolyte metabolism. The manifestations are localized because they are transmitted by the parasympathetic nervous system, reactions of the sympathetic system only being generalized (Otfried Mueller).

Best and Taylor[9] summarize the present views in the following words: "It is now generally accepted that the antigen-antibody reaction in some way brings about the liberation of histamine by the affected tissues and that the action of this amine is re-

sponsible for the allergic manifestations."

Magitot[10] describes how the irritation of the subepithelial layers leads to follicle formation in the mucous membranes and points out that the participation of the nervous system in an inflammatory process consists of stimulation of the sensory nerve terminals, whereby histamine is liberated, resulting in vasodilatation.

Histamine and adrenalin are antagonistic in their effect upon the capillaries, and adrenalectomized animals show an increased susceptibility to histamine administration. This fact may be an explanation of the beneficial effect of adrenalin in spring catarrh. It does not simply act as vasoconstrictor, thus alleviating the symptoms, but, as an histamine antagonist, it exerts its therapeutic action on a more basic level as well.

A considerable number of antihistamine agents have been found recently. One of them is riboflavin. It is known that this vitamin plays a rôle in the dehydration and destruction of histamine. It is a component of a diamino-oxidase which is essential in this process.

This has been proved experimentally by Doxiades and Lemke[11] who could desensitize guinea pigs against an allergic shock by previous administration of riboflavin. Kalter[12] has treated asthma successfully with riboflavin and has also had some success in the treatment of hay fever.

It has been shown by Daïnow[13] that nicotinamide also exerts a very beneficial influence on such allergic conditions as hay fever and asthma. In collaboration with Halpern,[14] he showed in animal experiments that guinea pigs can be protected from an asthma attack in an atmosphere containing histamine by premedicating them with nicotinamide. A similar attack of asthma provoked by acetylcholine cannot be prevented with nicotinamide. Halpern and Daïnow conclude from this that nicotinamide possesses a specific antihistamine property.

The same authors[15] showed that nicotina-

mide prevents and even relieves the spastic contraction of the isolated uterus and intestine of guinea pigs suspended in a solution containing histamine. In similar spasms caused by acetylcholine or the hormone of the posterior lobe of the hypophysis, nicotinamide failed to be effective.

In view of these experiments and clinical trials, it seems undeniable that riboflavin and nicotinamide are to be regarded as antihistamine agents. It is not surprising, therefore, that these substances are very effective in alleviating the symptoms of certain forms of spring catarrh, which, as has been shown, must be regarded as an allergic condition due to histamine liberation in the tissue.

Theoretically, the effect of nicotinamide on allergic conditions can perhaps be regarded as due to its regulating action on the cell metabolism as a prosthetic element of the dehydrating enzymes (cozymase). Colldahl[16] has shown that in experimental asthma of guinea pigs the lack of cozymase leads to a reduction of oxidative processes in the tissues which can be normalized again by administering this enzyme.

One can assume that histamine is not the only body responsible for allergic reactions and that other substances (acetylcholine, and so forth) also play a rôle. This may explain the fact that not all cases of palpebral spring catarrh were benefited alike from the administration of riboflavin by mouth, that the bulbar form did not respond at all. There must and will always be allergic conditions which will fail to respond to riboflavin or nicotinamide.

Moreover, one must always keep in mind that the therapy with antihistamine agents is a symptomatic therapy which does not remove the underlying cause for the allergic reaction but only alleviates its symptoms. Active antiallergic procedures, such as isolation from the guilty allergen or desensitization against it will remain paramount in the therapy of spring catarrh.

If and when isolation and desensitization

are not possible, however, we can regard riboflavin and nicotinamide as valuable allies in the symptomatic treatment of this annoying and sometimes even incapacitating disease.

OPHTHALMIC MINIATURE

The ophthalmoscope was discovered by Hermann von Helmholtz in December, 1850, and the account thereof was published in the following year. In speaking of this invention some years later, he said:

"The ophthalmoscope has become the most popular, perhaps, of my scientific achievements, but I have already told the ophthalmologists how luck played an incomparably greater part than my merit in this matter. I had to explain to my students the theory of ocular luminosity, which stemmed from Brücke. Actually, Brücke had missed the discovery of the ophthalmoscope by a hair's breadth. He had only neglected to ask himself the question: To which optical image do the rays returning from the luminous eye belong? Had he raised this question, he could have answered it just as quickly as I did, and the ophthalmoscope would have been discovered.... I immediately set about to construct the instrument out of spectacle lenses and cover glasses for microscopic preparations. At first it was quite difficult to use, and without a firm theoretical conviction that it must work, I would perhaps not have persevered in my efforts. But after about eight days I had the great pleasure of being the first to see clearly a living human retina."

THE REACTION OF VARIOUS TYPES OF FAT TRANSPLANTED INTO THE ORBIT OF GUINEA PIGS PRIOR TO THE DEVELOPMENT OF EXOPHTHALMOS*

GEORGE K. SMELSER, PH.D., AND V. OZANICS, M.S.

New York

Thyroidectomized guinea pigs receiving daily injections of extracts of anterior hypophysis develop exophthalmos which is accompanied by swelling and edema of the orbital and some fat tissues. These changes have been reported by several observers.[1-4] The edema, although noted in fat tissues other than in the orbit, is more marked there than in other regions such as in the perirenal or testicular fat bodies.[5] The reason for this difference is not clear and is of interest because of the importance of the role the edema may play in the production of the exophthalmos.

The edema of the orbit may be a local manifestation due to anatomic peculiarities of that region or, as suggested by Gailli Mainini,[6] a result of reduction in tissue pressure occasioned by the forward movement of the globe. If this concept is correct, the edema found in these animals should be restricted to the orbit, which, as has been shown, is not the case. Conditions in the orbit may simply exaggerate a generalized condition due either to factors as suggested by Gailli Mainini, or inadequate lymphatic drainage, and so forth.

Another possibility, which is in agreement with the available data, is that the permeability of the vascular bed varies with the tissue which it supplies, and that the vessels are not very permeable in these animals in the testicular, axillary, or perirenal fat but are in the orbital fat, as well as in the fat depots near the Fallopian tubes or the ureter.

These several concepts may be tested by transplanting fat from various parts of the body to the orbit and then producing an exophthalmos by the injection of anterior pituitary extracts. The histologic structure of the orbital fat of the intact and operated orbits could be compared with that of the graft and with donor type of fat tissue in its normal location.

If the transplanted tissue retained the characteristics shown in its original position, it would indicate that purely local orbital conditions were negligible in the production of the changes seen in the orbital fat of exophthalmic guinea pigs. If, on the contrary, transplanted fat were affected in the same manner as orbital fat, the importance of local factors would be emphasized. It was necessary, of course, to determine whether transplantation alone affected the response of the tissue to the injected extracts. Therefore, grafts of orbital fat were also made using as donors the male parent of the recipient.

EXPERIMENTAL

Forty-nine guinea pigs of both sexes were used in these studies. In seven cases, transplantation of fat to the orbit was done when the guinea pigs were young adults, in all others the grafts were made in 1- or 2-day-old animals. The Harderian gland which occupies a large space in the orbit was removed from the right orbit through a small conjunctival incision on the nasal side of the globe where its ducts open. The gland could be withdrawn from the orbit through this opening with a minimum of trauma and no bleeding save when the vessel to the gland itself was severed. The donor fat tissue was obtained from the same individual at this time and placed in the orbit. The con-

junctival incision did not require sutures. Donor tissue was taken from the right axilla in nine cases, the right testis fat body in 13 cases, the right ovario-uterine mesentery in 10 cases. Seventeen grafts of orbital fat were made in the same manner excepting that the transplants were from another, although related individual, rather than from the same animal.

The guinea pigs were thyroidectomized when several months of age and 7 to 10 days later daily injections of an anterior pituitary extract were administered to 39 of the animals. Representatives of each type of transplant, totaling 10 animals, were reserved as uninjected controls. The preparation and amount of extract administered was the same as reported in previous communications.[7, 8]

The length of the injection period varied widely; in some cases treatment was continued for 55 to 76 days. Eight animals, however, were injected for only 10 days. Each type of graft was represented in both long and short injection groups. Exophthalmos, as judged by inspection and postmortem measurement of the unoperated left eye, was present at the conclusion of the experiment.

At autopsy the fat in the operated orbit was carefully examined to determine if two (donor and host) zones could be distinguished, the tissue was then fixed in Bouin's fluid and histologic sections were prepared.

The block of embedded tissue was oriented so that the sections passed through both the host and transplanted portions and showed the interface between the two.

The removal of the Harderian gland and transplantation of fat in its place resulted in a variable displacement of the globe inward and slightly downward. The injection of the anterior pituitary extract caused an exophthalmos which was evident in the intact left side. Protrusion of the operated right eye was not as marked as that of the intact left eye and exact measurements of the exophthalmos (skull-limbus distance) made postmortem were not as dependable as usual, because of the displacement of the globe caused by the operation. However, the operated right eyes averaged 0.5 to 0.6 mm. greater protrusion postmortem than their controls.

All of the autotransplants were well incorporated in the orbit and had greatly increased in weight since grafting. Their growth was demonstrated in a few instances by comparison of the weight of the donor tissue at the time of transplantation with that obtained at autopsy.

The orbital fat of exophthalmic animals has a translucent appearance due to edema which differentiates it very sharply from the normal, dense, opaque character of ordinary fat tissue. This appearance was also characteristic of the native orbital fat in operated

Figs. 1 to 6 (Smelser and Ozanics). (Fig. 1). Section of orbital fat from an unoperated orbit of an exophthalmic guinea pig showing the edematous character of the tissue.

(Fig. 2). Section of transplanted orbital fat of an exophthalmic guinea pig. The graft had been made at birth and was from a related normal adult.

(Fig. 3). Section of orbital content of an exophthalmic guinea pig showing the interface between the edematous host orbital fat and the testicular fat transplant which remained unchanged by the pituitary extract injections and the development of exophthalmos.

(Fig. 4). Section of testicular fat in situ of an exophthalmic animal showing a region including some epididymal tubules. Note the presence of edema in the connective tissue surrounding the tubules and its absence in the purely adipose tissue.

(Fig. 5). Low magnification of a section through the orbital fat and graft of testicular fat of an exophthalmic guinea pig showing both the host and donor regions. Note that the host portion is edematous, whereas the grafted portion is not, except in the region of grafted epididymal tubules where edema is found. The situation is similar to that shown in Figure 4 where edema is noted near the epididymal tubules in testis fat in its normal location.

(Fig. 6). High-power view of the epididymal tubule region included in the graft shown in Figure 5.
orbits of the exophthalmic animals and contrasted sharply with the transplanted tissue of axillary, testicular, or uterine origin. Specimens of these donor-type fat tissues were removed from the appropriate regions, but from the side opposite that from which the fat used in making the graft had been removed. The orbital and transplanted fats of the 10 uninjected, control animals maintained the appearance of these tissues as observed in other thyroidectomized guinea pigs with intact orbits.

Gross observations of the orbits to which orbital fat had been transplanted did not reveal distinct separation of the fat into zones different in appearance or texture, and the entire mass appeared to be edematous. In a few instances it is possible that the major part, at least, of the graft had degenerated. This was indicated by a mass of dense connective tissue in the region where the implant had been made. In the other cases, however, the size of the homogeneous mass of fat in the orbit in the region of the graft together with the absence of scar tissue indicates that these transplants were well incorporated, and that the transplanted portion reacted to the injected pituitary hormone as did the original fat tissue of the host.

Sections were prepared of all the grafts as well as the orbital fat from the intact orbit and a specimen of the donor tissue. These where stained with Masson's trichromic stain, because with this stain the protein containing edematous infiltrate is particularly well shown. Sections of orbital fat from the intact orbits showed marked edema such as was reported earlier. Sections of the fat from right orbits which had been recipients of

orbital fat grafts showed two zones, both edematous. They were separated by a line of connective tissue forming an interface between graft and host. The histologic character of the two zones was similar and like the orbital fat in the unoperated orbits of the same animals (figures 1 and 2).

This condition was not found to apply in the case of the orbits containing grafts of axillary fat or in some cases from the testicular fat body or fat from the uterine mesentery. In these cases two distinct zones of fat tissue of different character were observed (figs. 3, 7, and 11). One was, in each case, typical orbital fat and the other was a mass of adipose tissue composed of solid masses of fat cells separated by a few delicate strands of connective tissue, characteristic of the fat depots from which they came (figs. 8, 9, and 10). The two masses of fat were separated by a band of connective tissue, as were the host and graft of orbital fat. In several cases the graft appeared to have been pushed into the host tissue and was partly surrounded by a narrow zone of edematous connective tissue, presumably of host origin.

Most of the grafts of testicular fat (13 cases) behaved exactly as did those of uterine mesentery or of axillary origin. Two types of fat were seen in these orbits, one edematous and containing nerves, vessels, and muscle fibers (retractor bulbi) characteristic of orbital fat, the other one not edematous but consisting of masses of closely packed fat cells containing a few strands of connective tissue (fig. 3). Sections of the fat from the testes of these animals did not exhibit evidence of the edematous infiltration,

Figs. 7 to 11 (Smelser and Ozanics). (Fig. 7). Section of orbital content of an exophthalmic guinea pig showing the interface between the edematous host orbital fat and the unaffected graft of axillary fat.
(Fig. 8). Section of fat from the axillary region of an exophthalmic animal. Note absence of edema even in the connective-tissue band.
(Fig. 9). Section of edematous orbital fat from the host zone shown in Figure 7.
(Fig. 10). Section through the transplanted axillary fat from the donor zone shown in Figure 7. Compare this tissue with the axillary fat in situ shown in Figure 8.
(Fig. 11). Low magnification of the orbital contents of an exophthalmic guinea pig showing the edematous native orbital fat and the unaffected grafted fat taken from the axilla.
with one exception, discussed later.

The fat from one orbit of an exophthalmic animal containing a testicular fat graft was not entirely similar to the others. The transplanted portion consisted largely of solid nonedematous fat as did the others but in the center of this mass, apparently unconnected with the host orbital fat, was a group of epididymal tubules which had been taken with the transplant by accident (fig. 5). They lay in loose connective-tissue network which was distended and infiltered with a protein containing edematous material similar in texture and staining reaction to the edema of the orbital fat (fig. 6).

Sections of one testicular fat in situ of another injected guinea pig also passed, by chance, through some of the epididymal tubules. These tubules were supported by a loose connective-tissue framework which contained an edematous material similar to that seen in the orbital and in the transplanted testicular fat of the case already mentioned (fig. 4).

DISCUSSION

The data reported strongly supports the concept that the condition of the fat tissues found in exophthalmic guinea pigs is due to some basic characteristics of the tissue and/or its vessels, rather than to its location or the peculiarities of its site, such as lymphatic drainage. Since the transplants of orbital fat to the orbit reacted exactly as did native fat in both operated and intact orbits, it would appear that the act of transplantation did not interfere with the changes brought about by injection of the extracts. The transplanted tissues of all types maintained themselves and grew, rather than were replaced by growth of the host tissue, because two distinct masses of fat were found separated by a band of connective tissue.

In a few instances, not included in the reported cases, a graft of orbital fat obviously did not persist. In such cases the orbit contained some, presumably, native fat and a mass of scar tissue located in the region of the orbit where the transplant had been made. The orbital fat found was situated within the muscle cone and was traversed by the retractor bulbi muscles and ciliary nerves in the manner characteristic of the normal orbital fat.

Axillary, uterine, and testicular fats were transplanted under more favorable conditions than were the orbital fat grafts since they were autotransplants. All were well incorporated and had increased in mass in the orbit, but were unaffected by the injected extracts. They remained in a normal condition, as did the fat of their types in the normal environment. In an earlier study it was reported that fat in the axilla was not changed in a manner similar to that noted in the orbit. Fat from the region near the Fallopian tubes, however, was affected, indicating that the edema produced by injection of anterior pituitary extracts was not limited to the orbit, but was found in some other tissues and was absent, or very scant, in others. This observation was confirmed in the present experiments.

Dobyns's[9] report that testicular fat was modified in similar experiments performed by him is in essential agreement with cases reported here, for, although in most instances the sections of testicular fat studied showed no structural change from normal, they were only through that portion of the testicular fat body which contained very few connective-tissue septa and no epididymal tubules.

Obviously edema does occur in at least a restricted portion of the testicular fat of the experimental animals. This observation emphasizes the conclusion reached in the study of the other facts, namely, that transplanted tissues behave in the orbit in the same manner as they do in their native environment. Grafts of the nonreacting part of testicular fat were unaffected in the orbit by the injected extracts; whereas, that portion which became edematous in the scrotum also became edematous in the orbit.

SUMMARY

1. The injection of anterior pituitary extracts into thyroidectomized guinea pigs produces an exophthalmos and an edematous condition of the orbital and some other fat tissues.

2. Orbital fat which has been transplanted to the orbit is affected in the same manner as the native orbital fat.

3. Fat which is unaffected in its normal location by the injection of anterior pituitary extracts retains this characteristic when transplanted to the orbit, although the grafts are well incorporated and have increased in size.

4. Fat tissue which is affected in the pituitary-extract treated animals also becomes edematous when transplanted to the orbit of appropriately treated animals.

5. These data are interpreted to suggest that the edema of the orbital and other fats caused by the pituitary extracts is due to conditions peculiar to those tissues and their vascular supply, rather than to their location in the body.

LEPTOSPIRAL UVEITIS*

HAROLD A. HANNO, M.D.
Philadelphia, Pennsylvania
and
ALBERT F. CLEVELAND, M.D.
Drexel Hill, Pennsylvania

Of the many pathologic conditions which are known to give rise to disease of the uveal tract, one of the more rarely encountered and less frequently recognized is Weil's disease or Leptospirosis icterohemorrhagica, only 222 cases of which have been reported in the United States literature.[1]

Weil's disease is an acute systemic infection. The etiologic agent is the Leptospira icterohemorrahgicae, a spirochete found commonly in rats, and less frequently in dogs, mice, cats, and other animals. Human infection usually occurs from contact with stagnant waters contaminated by murine excreta, the portal of entry usually being the abraded skin, although infection may occur by way of the gastro-intestinal tract, the nasal mucosa, or the conjunctiva. The disease is especially prevalent in those working in rat-infested environments: sewer workers, fish and poultry handlers, miners, butchers, tunnel diggers, and so forth. Clinically the disease is characterized by a sudden onset with headache, fever, prostration, and myalgia. In the more severe cases, jaundice occurs, and hemorrhagic phenomena and evidences of renal impairment are present. In the milder and anicteric cases, diagnosis may be difficult, and it is undoubted that many go unrecognized.

Diagnosis may be definitely established by the isolation of the causative organism from the blood or urine, and by the demonstration of specific lysins and agglutinins in the serum. A positive agglutination in a titer of 1:300 or above[2,3] or a complement fixation titer of two units or more[4] is considered diagnostic of Weil's disease. Death is extremely rare in the anicteric cases, but the fatality rate in some epidemics of Weil's disease has been as high as 30 to 48 percent.[2,3] Penicillin is a specific therapeutic agent. Streptomycin and aureomycin are also drugs of value in this condition.

The eyes are commonly involved in Weil's disease. Early in the course of the illness conjunctival injection is the rule.[2,3,5-8] In some cases a catarrhal conjunctivitis[6] and petechial hemorrahges in the conjunctivas[3] may be present. Patterson[9] found conjunctivitis and episcleritis in every one of a series of 37 cases of Weil's disease which he studied. A mild form of iritis or iridocyclitis frequently occurs late in the disease, appearing between the 16th and the 42nd day.[5] The frequency with which the anterior uveal tract is affected is variously reported at from 3 percent[7] to 44 percent.[5,8] Hypopyon has been noted.[7] The posterior uveal tract is rarely involved.[6] The retina may show congestion and small hemorrhages, and occasionally optic neuritis may occur.[6] Orbital pain due to involvement of the extraocular muscles is occasionally present.[10]

CASE REPORT

Because of the uncommonness of established cases of Weil's disease in this country, and the unusual features of a case which was recently seen, the following case report is presented.

History. C. S., a 26-year-old Negro, was admitted on September 27, 1947, to the ophthalmologic service of Dr. James S. Shipman at the Wills Hospital with the chief complaints of some blurring of vision and the presence of streaks and spots in the fields of vision in both eyes. He stated that he was well until a month previously, when he de-

veloped fever, sweating, chills, headache, generalized malaise, and anorexia, his temperature going up as high as 102°F. After a week of pyrexia, his fever subsided and he noted jaundice. Two weeks later, while his jaundice was still present, his eye complaints began. He was afebrile after the first week of his illness.

Physical examination on admission revealed a well-nourished, young Negro in no acute distress. There was no fever. A moderate degree of conjunctival icterus was noted. The lungs were clear, and the heart showed no abnormalities of note. The liver edge was palpable one-finger's breadth below the right costal border and the spleen was not demonstrably enlarged. No hemorrhagic phenomena were noted.

The vision was: O.D., 6/60; O.S., 6/21. Both pupils were dilated and fixed, and there were numerous keratic precipitates of various sizes on the posterior surface of both corneas. A positive flare and some small pigmentary changes on the anterior and posterior lens surfaces were noted. Because of the presence of numerous thready, floating, vitreous opacities, the details of the fundus could not be well visualized.

The hemogram revealed an erythrocyte count of 3.02 millions with a hemoglobin of 62 percent and a total leukocyte count of 7,100, with 63 percent mature polymorphonuclear leukocytes, 3 percent stab forms, 8 percent eosinophiles, and 24 percent lymphocytes. The color index was 1.0. No sickling of the red blood cells was seen. The fasting blood sugar was 71 mg. precent, and the serum bilirubin was 1.0 mg. percent with a delayed direct reaction.

The prothrombin index by the simple bedside test was 63 percent, and the cephalin flocculation was plus 2 at the end of 48 hours. The sedimentation rate by the Westergren method was 25 mm. per hour. The agglutination reaction for B. abortus was negative. The erythrocyte fragility revealed that hemolysis began at 0.42 and was incomplete at 0.28.

The Wassermann reaction and the intradermal Mantoux test were negative, and a prostatic smear showed no evidence of infection. X-ray examination of the chest revealed no evidences of any active pulmonary disease. Slight mucosal hypertrophy of the left ethmoid cells was noted on X-ray study of the nasal accessory sinuses. No evidences of dental infection were found on roentgen examination. Otorhinolaryngologic consultation revealed only deviation of the nasal septum and minimal tonsillar disease.

Course in hospital. It was felt upon admission that the patient's jaundice resulted from a subsiding infectious hepatitis and, as a consequence, fever therapy was felt to be contraindicated. He was treated conservatively for his eye disease with atropine, and for his suspected liver disease he was placed on a high carbohydrate, high protein, low fat diet with multivitamins.

He was afebrile during the course of his hospital stay except for a mild temperature rise during his first hospital day as a result of an initial dose of typhoid vaccine which was administered on admission. The jaundice gradually disappeared and satisfactory recovery of vision and clearing of the media occurred.

The patient was discharged from the hospital on October 10, 1947, with vision with pinholes of: O.D., 6/15—1; O.S., 6/12—2.

He returned to the medical clinic on October 22, 1947, at which time no icterus was discernible and the liver and spleen were not palpable. A bromsulfalein determination showed a retention of less than 5 percent with the 2 mg. dose after 30 minutes, and the serum bilirubin was 0.3 mg. percent.

Serologic studies. Questioning at this time elicited the information that until the onset of his acute febrile illness, the patient had been working as a member of a construction gang engaged in the tearing out of an old sewer and the installation of a new one. Because of this occupational history, it was suspected that the illness from which the patient had recovered might have been a leptospiral infection.

Serologic studies at the Graduate Hospital, Philadelphia, revealed a positive agglutination in a dilution of 1:1,000* and a complement fixation titer of 3.75 units for the Leptospira icterohemorrhagicae, both strongly positive reactions. The cephalin flocculation at this time was negative after 48 hours, and the hemogram revealed an erythrocyte count of 4.31 millions with a hemoglobin of 72 percent and a total leukocyte count of 10,300 with 76 percent polymorphonuclears, 5 percent eosinophiles, 2 percent basophiles, and 17 percent lymphocytes.

Iridocyclitis. The patient's ocular condition continued to improve on his periodic visits to the eye clinic, and the vision on December 26, 1947, was 6/9 + 2 in either eye. On February 10, 1948, however, an acute iridocyclitis recurred in the left eye. He was readmitted to the hospital the same day with vision of: O.D., 6/9; O.S., 5/60.

Examination revealed the presence of numerous punctate keratic deposits in the left eye. There was marked turbidity of the aqueous and numerous cells were present in the anterior chamber. The vitreous contained large varishaped opacities. Central visual fields in the left eye showed a quadrantlike cut in the upper temporal area with a 1-mm. test object.

Additional serologic studies at this time revealed a positive agglutination in a dilution of 1:1,000* and a complement fixation titer of 4.5 units for the Leptospira ictero-

hemorrhagicae. A course of penicillin therapy totalling 5,000,000 units given at 3-hour intervals over a period of 12 days was administered, and the patient's uveitis became quiescent. He was discharged from the hospital on February 23, 1948, with visual acuities of: O.D., 6/6; O.S., 6/12.

The patient's progress was followed periodically in the out-patient clinic. When he was last seen on May 28, 1948, there was no injection of either eye. Both irides were active and free of synechias. Very few keratic deposits were present. No anterior chamber abnormalities could be found, and the vision in each eye was 6/6.

COMMENT

The case reported above represents an instance of a mild case of Weil's disease complicated by a bilateral iridocyclitis with some evidence of posterior uveal involvement. The eye findings dominated the clinical picture and constituted the presenting complaint which brought the patient to seek admission in an eye hospital. It is of interest that the patient's occupational history furnished the clue to the diagnosis.

The diagnosis of Weil's disease rests upon a high index of suspicion. The possibility of Weil's disease should be thought of by the ophthalmologist in any patient with iritis or iridocyclitis accompanied by or preceded by fever or jaundice, particularly in those patients whose occupations bring them into contact with rat-infested surroundings.

1737 Chestnut Street (3)
1216 Morgan Avenue.

LIMITS OF STEREOPSIS DUE TO PHYSIOLOGIC DIPLOPIA*

PAUL W. MILES, M.D.
Saint Louis, Missouri

In the ordinary two-line tests for stereopsis, the ability of the subject to detect the difference in distance of the lines from the eyes increases indefinitely with the increasing nearness of one line. Obviously, at some point, physiologic diplopia occurs, just as a spot on the window pane appears double when one observes a tree outside, and the tree appears double when one observes the spot. One is not commonly conscious of physiologic diplopia becouse of suppression of one of the two retinal images.

Does physiologic diplopia interfere with stereopsis? There has been to date no evidence that it does. A crossed physiologic diplopia, where the left image is seen by the right eye and the right image is seen by the left eye, has been believed to produce a strong binocular clue for nearness. An uncrossed diplopia was believed to produce a clue for farness.

This paper presents experimental set-ups where more than a certain amount of difference in the distance of vertical line targets from the eyes causes a deterioration of depth judgment. The evidence suggests that imperceptible degrees of physiologic diplopia are enough to interfere with stereopsis.

This new phenomenon is interesting to ophthalmologists for several reasons: It gives evidence on the extent of Panum's fusional areas. It adds a new factor to consider in devising instruments to test steropsis. It helps to explain difficulties some patients have at first with the space eikonometer, which is a rapid test for stereopsis on line targets. It will modify the technique used in testing aniseikonic patients.

EXPERIMENTAL TECHNIQUES

EXPERIMENT I

In the summer of 1946, A. Ames, Jr., of the Dartmouth Eye Institute devised a new target for testing patients with aniseikonia which he asked me to try on patients already tested with other instruments. This target, illustrated in Figure 1, consisted of luminous
Fig. 1 (Miles). Rectilinear luminous grid targets, devised by A. Ames, Jr., for measuring aniseikonia which showed defective stereopsis with increasing physiologic diplopia.

rectilinear grids placed at eye level 14 feet from the eyes. These grids, made on black-painted glass by scratched lines, were placed on a box containing fluorescent lamps. The

grids measured 16 by 24 inches, and were mounted face to face 8 feet apart.

The patient was placed with head fixed in position as indicated in Figure 1, in complete darkness, with his refractive prescription before his eyes. He was asked to look from one of the grids to the other and report which appeared nearer. Then the two grids magnification exceeded 0.75 percent. Patients were unable to localize the targets in space until their size prescription, within about 0.75 percent, was placed before their eyes. At the time, it was believed that the difficulty was due to one grid geometrically approaching the patient's face absurdly near, causing the patient to discard binocular clues.

were equated by placing, by hand, size lenses (axis-90°, magnifying afocal lenses) before the eye on the side where the grid appeared nearer. Then, the sensitivity of the patient was determined by finding the smallest size lens which would make a perceptible difference in distance of the two grid targets.

Twenty-four known aniseikonic patients were tested in this way. Four were insensitive, and the others were highly sensitive to small size lenses, but insensitive to size lenses magnifying more than 0.75 percent. The conclusion was that the target was more sensitive than the space eikonometer target to small differences in magnification, but that something destroyed sensitivity when the

EXPERIMENT II

The present experiment began as a study of stereopsis in the dark-adapted individual. When the first subject showed excellent stereopsis on a two-line test at 2 meters with one line moved back and forth 2 cm., but none at all when the line was moved 3 cm., it was realized that the same phenomenon elicited by the luminous grid targets was occurring.

The apparatus consisted of the ophthalmoeikonometer instrument, table, and hydraulic chair, and a target consisting of two miniature ophthalmoscope lamps mounted instead of the usual two lines in stereopsis tests.

The lamps were wired in series with 7.5 volts A.C. producing constant maximum brightness. A large piece of red Maddox-rod glass was placed before both eyes about 15 mm., so that the two small points of light appeared as two bright-red thin vertical lines without ends. The ends extended up and down about 45 degrees, but changed so with vertical eye movements that they could not serve in depth judgment. Nothing else in the room was visible in the 45-degree field straight ahead. Room illumination came from a diffuse source overhead. In Subjects 1 and 2, Table 1, the light was turned on bright for the light-adaptation test, and completely off for the dark-adaptation test. In other subjects, the overhead illumination was quite. dim, so that the buff walls reflected only about 0.2 foot-candles on a light meter at eye level.

The set-up can be seen diagramatically in Figure 2. The two lamps were at "0" and "Fixation," and were 36.2 cm. apart, 192 cm. before the corneas. The usual variable axis-90° size lenses were used before each eye to introduce the disparity. The effect of separation of an afocal combination of minus and plus axis-90° cylinder to magnify the images seen by one eye is seen in Figure 2. With interpupillary diameters from 60 to 68 mm., the size lenses produced the effect of moving the luminous line at "0" back and forth at intervals of 9 to 11 mm. In the diagram, fixation is limited to the right line target, which is placed in the optical axis of the size-lens combination. The eyes were free to move from one to the other line target, in which case the disparity changes eyes but maintains equal angular space relationships. Slight movements of the head were prevented by the head holder but did not change the apparent distance of either line in any position of the size lens.

On the retina of the right eye in Figure 2 is seen the exactly corresponding point "0," and the disparate points from plus to minus 3. In the past, the diplopic images

on each side of "0" were said to produce a "near" clue to depth, if temporal, and a "far" clue, if nasal, to the corresponding point.

In Figure 2, the retinal point "0" of O.S. corresponds exactly to point "0" of O.D., but the points from minus to plus 2 in O.D., although not corresponding, may fuse with "0" producing a stereoscopic cerebral image and perception of depth. These disparate
Fig. 2 (Miles). Diagram of experiment on stereopsis using luminous line targets at "0" and "Fixation." Stereopsis was found defective when the lines were placed at minus-3 or plus-3 positions.

images which fuse correspond to Panum's fusional areas, which exist before and behind the horopter, in which physiologic diplopia must be present but is imperceptible. The points minus and plus 3 outside this area may or may not appear as diplopic images, according to the attention or imagination of the observer.

The subject was seated before the apparatus, and the pupils aligned with the optical centers of the variable size lenses. The target was tested each time to insure that the subject could see both target lines equally well monocularly with each eye at all positions of the size lenses. The right size lens was set at 2 percent, and the left

was then adjusted until the subject reported the two lines appeared equidistant from the eyes.

The right eye was covered by the examiner's hand, while an adjustment of the right size lens was being made to any of

and none volunteered that the lines ever appeared blurred or doubled.

All subjects had normal vision except U. L., who had 6/7.5 in the left eye. Four wore glasses. Two subjects, E. G. and B. T., had no stereopsis by the Maddox-rod test,
Fig. 3 (Miles). Sixteen judgments of each position presented graphically in Case 1 (M. B.). "E" represents the expected curves if stereopsis improves with distance differences of targets.

the seven different settings used. Setting intervals, to produce the target movement described, were 0.50 percent. Any change of 0.50 percent in the size lens made an apparent movement of one target about 10 mm. by calculation. The setting made, the hand was removed to let the subject see binocularly. Sixteen judgments as to which line appeared nearer were required for each of the seven settings. The settings were presented in random order, with care that the subject got no clue whatever as to which direction the size lens was changed. The subject was required to guess right or left, if the target lines appeared equal. No suggestion of diplopia was made to the subject,

although by usual tests it was normal. Results on 14 subjects are shown in Table 1. The plus- and minus-3 positions in the last eight subjects were made four times the 10-mm. interval, instead of three times. This was done in the hope of exaggerating the phenomenon and to decrease the chance that it is simply an experimental accident.

Figure 3 expresses graphically the results on Subject 1, compared to "E," the curve described previously by K. N. Ogle[1] in studies of sensitivity to changes in the space-eikonometer target position. According to "E," the nearer one target line is to the observer, the higher statistical chance there is of 100-percent correct judgments.

Figure 3 shows, in curves L.A. and D.A., that, when the two target lines were actually equidistant, the subject was declaring the right line nearer just as often as the left line nearer (R8-L8).

When the right or left line was brought 10 mm. nearer, the judgments made were 75-percent correct (R12-L4) (R4-L12) in each case, and, when brought 20 mm. nearer, the judgments were 62.5-percent correct. When the right or left line was brought still nearer, 30 mm., the judgments were again only 50-percent, which indicates no stereopsis.

In other words, M. B. had the best stereopsis when the disparity was least, and the worst when the disparity was greatest. From her horopter at 192 cm., Panum's fusional area was about 20-mm. wide. Of the 14 subjects, only four failed to show this phenomenon and, of these, two had no stereopsis with this type of test.

In Figure 3, the solid line L.A. refers to light adaptation, and the dashed line D.A., dark adaptation. Results are not conclusive, because the target background contrast is different in the two conditions, undoubtedly affecting stereopsis.

M. B. was tested again in the same equipment without the Maddox rods, without the size lenses, and using an apparatus with vertical line targets of the same separation at the same distance, introducing the same disparities mechanically. The vertical lines were aluminum wire about 3.75 mm. in diameter. A mask, 33 cm. before the eyes, obscured the ends of the wire in all positions. With the room illumination dim, and the background a painted black screen, no details were visible in the same 45-degree field as with the Maddox-rod tests. Results in the analogous positions were as follows:

-3	-2	-1	0	$+1$	$+2$	$+3$
0 16	1 15	2 14	4 12	9 7	6 10	10 6

The data are skewed, but no decrease of stereopsis occurred at the extremes.

This test was repeated with an aluminum background to decrease the contrast of the aluminum test objects, and the following resulted:

-3	-2	-1	0	$+1$	$+2$	$+3$
1 15	3 13	1 15	4 12	5 11	10 6	14 2

DISCUSSION

The Maddox-rod line target for measuring stereopsis gives different results from those of other targets. One may review all known clues to depth perception, and find no difference between the two types of test. M. B. was tested on the aluminum rods monocularly and made largely incorrect judgments, confirming Howard's finding[2] that retinal image size difference is not a sufficient clue. Neither type of test involves different illumination of the two line targets. Parallax, overlay, perspective, and haze are ruled out. There cannot be much difference in convergence upon alternating fixation on the two lines of either type of target. Even if there is, convergence has been shown to be a poor clue to depth perception.[3]

There is definitely something about vertical luminous line targets which accentuates physiologic diplopia or prevents fusion of disparate images. The Maddox-rod line has no definite breadth when the light source is small, and it is an ideal straight line. One is reminded of the comparison of resolving power using two points with resolving power using two straight lines. The lines can be distinguished with 10 times more precision. It is the principle of the vernier, which is used in all precision measuring instruments.

Conclusive evidence that the thin straight-line concept produces the phenomenon described in this paper is found in use of the frontal plane apparatus[4] for measuring aniseikonia (fig. 4). This target is the complete opposite of the straight line, since it consists of irregular ink blots. When the target plane is placed at zero on the scale and observed from the position indicated by the head holder, it appears on a true frontal plane. When axis-90° size lens is placed before one eye, the plane appears to rotate on

its central vertical axis and will continue to rotate further with increasing magnification until about 25 percent has been attained. At this point, the frontal plane has rotated about 60 degrees. This high fusional amplitude of obviously disparate images is due to the irregular ink-blot type target which, although highly distorted, the cerebral centers will fuse. The Maddox-rod straight lines

judgment were found. Results on W. H. L., M. D., vision 6/6 without glasses were:

-3	-2	-1	0	$+1$	$+2$	$+3$
11 5	12 4	9 7	14 2	14 2	13 3	16 0

With increasing nearness of the right target, judgment became worse and worse.

The possibility that stereopsis might again improve with still more increase in the binocular disparity was not studied in these
Fig. 4 (Miles). Frontal plane apparatus. The irregular ink-blot target will not accentuate physiologic diplopia like luminous vertical line tests do. The amplitude of this target is about 25-percent magnification, compared to about 1.5 percent for vertical line targets, before stereopsis deteriorates.

undergo diplopia at about 1.5 percent with loss of stereopsis.

The experimental findings described in this paper were found under conditions of artificial aniseikonia. The defects in fusion due to unequal sized images from the two eyes are well known. The artificial aniseikonia is not believed to be a factor in the present experiments because the Maddox-rod line target is of such indefinite thickness. The thickness varies constantly with the eye movements and, frequently, the line which appears slightly thicker is definitely more distant during tests.

However, to make certain, four subjects were tested with Maddox-rod targets in which the light bulbs themselves were moved mechanically. The same difficulties in depth

experiments. However, there is a suggestion of such a trend in Subjects 1 and 6, in Table 1. Theoretically, it would not be expected unless parallax, or perspective, or size clues crept into the experiment.

SUMMARY AND CONCLUSIONS

An experimental set-up is described in which more than a certain amount of difference in the distance of two vertical line targets from the eyes causes a deterioration of depth judgment. Tests were performed on 14 subjects with apparently normal eyes and normal stereopsis by the ordinary tests. Each subject was tested on a two-line target with the lines in seven different relative positions with 16 trials in random order of each position. Target distance was 192 cm., lateral

separation was 36.2 cm., and the variation of one line nearer or further was in three steps of about 10 mm. each, depending on the interpupillary distance.

This phenomenon is characteristic of thin vertical line targets and does not occur in the ordinary tests for stereopsis.

The evidence apparently modifies Hering's laws of stereopsis:[3] (1) That depth judgments are directly dependent on the magnitude of the retinal disparity, which is the deviation from strict retinal correspondence in normal binocular vision. (2) That depth judgment from noncorresponding points seen in physiologic diplopia is "far" for images falling nasally, and "near" for images falling temporally on the retina.

The extent of Panum's fusional areas at a fixation distance of 192 cm. is about 20 mm. from the horopter.

When testing patients on the space eikonometer, who do not immediately project the target properly or who do not appear sensitive to changes in the size lenses, one should consider that the stereopsis limit due to physiologic diplopia as described in this paper is being exceeded and that trial and error changes in the size lenses are advisable to pick up the target position in which the patient is sensitive.

A SIMPLE, MORE ACCURATE MEANS OF CHARTING VISUAL FIELDS

GEORGE ZUGSMITH, M.D., AND IRVING REHMAN, PH.D.
San Pedro, California

The first concept of perimetry was elaborated by Euclid,[1] who taught that a fluid streamed from the eye in the form of a cone with the apex in the pupil and the base on the object being looked at. The base comprised the visual field.

The field of vision was first illustrated by Ulmus of Padua in 1602. However, no further information regarding this subject appeared until the article of von Graefe in 1856.[2]

Many attempts to chart visual fields accurately have been made since the introduction of modern procedures about 50 years ago, as evidenced by the numerous articles published. The first perimetry was done with an illuminated object. In 1884, Abertotti used a "fluorescent" test object. In 1889, Bjerrum[3] stated that using one test object was like using only the 20/40 line for vision testing. He advocated multiple testing with various sized test objects. This was the method that prevailed until 1933 and to a large extent has prevailed since.

However, in 1933 Mayer,[4] seeking for a more adequate and reliable type of test, described the visual-field test done with a minimal light stimulus. In reviewing Mayer's work and the subsequent literature, it was found that his work had not been developed further, by himself or others.

In 1935, Mayer[5] described a means of

perimetry utilizing an apparatus for producing a minimal light stimulus of measured interval duration. His apparatus consisted of a condenser discharge into a neon bulb, thus producing a flash of very short duration and fixed intensity.

The apparatus was expensive and cumbersome. The flash of the neon was red and Dr. Mayer states that tubular fields were not present with this light stimulus. He also stated, "Varying slightly with the person tested," the speed of the flash, 0.033 second, is so rapid as to be lost at the 50- to 60-degree meridians. As more peripheral meridians are approached, the flash is lost at lesser speeds.

Thus, it was concluded that Dr. Mayer was endeavoring to find a much more quantitative visual-field test. He stated, however, that the advantages of this type of stimulus are that it is critical and it eliminates a moving target.

A moving target, in itself, has definite inherent disadvantages: (1) There is much poorer control of fixation however good the fixation device; (2) there are variable effects of previous exposures on the sensitivity of the retina; and (3) there is a time error which cannot be standardized.

The criticisms raised by Mayer and his attempt to remedy the disadvantages are readily apparent when one considers the apparatus he developed and its inherent difficulties.

DEVELOPMENT OF NEW APPARATUS

Our own objective was to get a simple, inexpensive, reliable machine which would render visual field taking easier and more accurate and would dispense with multiple test objects. In an effort to achieve a more reliable test object (light) for perimetry, an inexpensive apparatus was developed by the Chart-lite Instrument Company of Los Angeles. This instrument produces a pulsing light in the form of a flash of measurable duration, which can be accurately controlled and easily varied in intensity and frequency.

The usual technique may be employed in determining visual fields with slight variations. Our technique was to move the light slowly from the periphery to the fixation point, moving more slowly or stopping at the critical point in the field where the light was observed. A movement of one-half inch at this point, in most cases, eliminated the light or made it appear. There was no hesitation or indecision on the part of the patient, because the flash is clear cut and definite. This same advantage holds for central fields. These were taken on the Gruss tangent screen. The blindspots, when outlined with this apparatus, are better than textbook illustrations.

Another refinement, which we were able to introduce, was in the cases of poor central fixation. In these cases the central target for fixation could be made any size. We have used a white disc 12 inches in diameter with crossed lines. The patient fixes easily and yet the scotoma is beautifully outlined because the pulsing light passes from black on to the fixation target without disturbing the patient's fixation.

The fields were taken on the optical perimeter and on the tangent screen, using the same arm to hold the light, and the perimeter was painted black. The optical perimeter is the one mentioned previously, as constructed under the supervision of Ferree and Rand.[6] Two arcs of the same radius of curvature were constructed at right angles to each other—one, a 180-degree arc, the perimeter arm; the other, a 90-degree arc, the lamp arm, at the end of which is placed the source of light. The two arms are fastened together at the center of rotation.

A housing shields the lamp from the patient. This housing is made of black japanned iron and is painted a mat black on the inside in order that all of the light that passes to the perimeter arm will, as nearly as possible, radiate directly from the lamp filament.

Its dimensions are 4¼ by 4¼ by 5 inches. Filtering the light to daylight quality is accomplished by using as a source of light a well-seasoned, 75-watt type C_2 (blue bulb) Mazda lamp operated by ammeter and rheostat control. The surface of the bulb is acid-etched to diffuse the light.

A chin rest on a tridirectional stand is placed at a distance of 33 cm. from the central fixation point, which is the center of these intersecting arcs. The horizontal arc is marked in degrees up to 90 in two directions from the center. Fixation is controlled by sighting through the hole of the bisecting arcs. A movable ratchet allows for the eye of the observer to be regulated at the 33 cm. distance from the fixation point. Seven and a half foot-candles is the amount of light generally recommended and is controlled by the ammeter and rheostat mentioned previously.

The light test object consists of a six-volt straight filament bulb that produces a very even and efficient source of illumination. This light is mounted on an 18-inch rod that serves as a light wand. A flexible wire permits complete freedom of motion of this light source (wand) in determining the visual fields. The wand is coated with a non-reflecting black lacquer to eliminate possible reflections resulting in false readings; our perimeter being black, the same wand is used for tangent-screen work. For perimeters of a gray color, a wand of the same color may be substituted.

In order to make this procedure utilizing the light technique comparable to that employing multiple test objects, it became necessary to be able to vary the intensity of the test light. This has been incorporated into the instrument so that the light intensity may be varied from zero or no light to an intensely bright light. The intensity range is gradual from zero to bright so that extremely small increments may thus be obtained.

A means has also been included to vary the speed or frequency of pulsation or flash-ing of the light. Four speeds have been found to be optimal in the results they produce; that is, flashes occurring at intervals of one second, one-half second, one-third second, and one-quarter second. Provision has also been made for manually controlling the rate and duration of the pulse so that the intensity, frequency, and duration of the flash may be varied to any desired pattern, each one completely variable and independent of each other. The instrument is very compact, is about six-inches square, and is readily portable (fig. 1).

Comparative tests were made with this instrument on a number of cases for charting
Fig. 1. (Zugsmith and Rehman). A new instrument for charting visual fields.

normal visual fields and these were plotted against the various sized test objects normally used. The technique of using a pulsing light was found to be quite simple. Since the flash is of definite intensity and duration and the target is stationary in nature, the patient error is minimized or eliminated.

The calibration was difficult since we were unable to obtain a light meter which would record the intensity of the flash in lumens or foot-candles because the duration was so

short as not to be able to overcome the lag or latent period of the various meters used. We found an arbitrary point of intensity on our machine which was comparable to the 1-mm. white test object.

Reeves[7] has estimated the least amount of radiant energy which would excite the retina sufficiently to give rise to a perception of light. This light is well above this minimal stimulus, but not high enough to produce an after-image. It has been shown that the rods are the rapid organs and the cones are the slow factor in the reaction to light[8] and a flash as rapid as the one used will not exhaust the retina.

SUMMARY

A mechanism is presented, which is inexpensive and yet more reliable and more accurate than the test objects. The patient finds this test easier and more definite than one with nonluminous test objects and the physician has, at the turn of a control, various sized objects for both perimeter and tangent-screen work.

THE LEARNING PROCESS IN ORTHOPTICS*

JULIA E. LANCASTER, M.A.
San Francisco, California

The visual act has two distinct parts. One part consists of the mechanism for receiving an image with each eye, the other part consists of the means by which the two images are coördinated and interpreted in the brain. From another point of view, binocular vision may also be considered to have two parts; an innate structural, reflex part, which matures in the normal growth process, and a more complicated part which requires use, experience, and interpretation to develop fully.

Orthoptics is concerned with developing normal binocular vision and is almost entirely limited in its applications to this second field of development; that which takes place by use and interpretation and the acquisition of binocular skill. Orthoptics cannot alter growth, it cannot change, as can the surgeon, anatomic and pathologic conditions which prevent the normal maturing of each eye. It can only work with the kind of eyes ophthalmologists have been able to obtain for the patient by occlusion, refraction, surgery, or other treatment. It is then the function of orthoptics to help the patient acquire the best binocular skill of which these eyes are capable.

If there is some insuperable obstacle to binocular vision, such as a permanent amblyopia or an uncorrectable deviation, it is beyond the possibilities of orthoptic training to obtain normal binocular vision in such cases. Fortunately, for ophthalmic progress, many conditions once thought insuperable are now correctable, and binocular vision is becoming correspondingly more frequently attainable.

BINOCULAR VISION PERFECTED BY LEARNING

The process by which binocular vision is perfected is the learning process. This is true whether it is acquired in the normal development of the child or by deliberate training in orthoptics. Learning is purposeful adaptation to environment, to the constant stimuli which the organism is receiving. Since it is innate in the organism to respond to stimuli, learning consists of making responses which are an effort to make useful adaptations.

If such adaptations are successful, they are accepted by the individual as useful learning and are repeated each time the stimulus is received. If they are unsuccessful, they tend to be discarded and something else is tried next time. Thus learning becomes a kind of trial-and-error.

The learning of visual skill is no exception. The growing infant experiments with the various aspects of the visual act. For the safety and welfare of the individual, it is highly important that he acquires a clear single image. Hence the mechanism for achieving it is mostly innate and develops at the reflex level.

Some portions of the mechanism are not mature at birth, and it takes nearly eight years before full growth and visual acuity are achieved but, as the correct age is reached, each factor in the growth pattern matures, ready for use.

If, during the growth and learning period, anything interferes with the opportunity to get normal use and experience, the visual act will not come to normal completion. It is also true that if, after normal skill is acquired, something interferes with constant practice of the skill, it will not be maintained and may decrease. It will certainly not improve.

It is, therefore, of the utmost importance that the growing child shall first get enough practice and use of each eye to permit the innate growth processes and reflexes to come to maturity; secondly, get the practice in

binocular skills necessary to learning to use both eyes correctly; and finally, have opportunity for abundant interpretive experience.

LEVELS OF LEARNING

Learning is essentially a stimulus-response mechanism. It differs from the simple reflex by the highly complicating factor of the emotions and the intellect or cortex of the brain. Strictly speaking, learning may take place at four different levels: (1) The somatic or body-growth, (2) the neuromuscular or reflex, (3) the intellectual or cortical, and (4) the emotional.

Because of the innate and hence nonmodifiable character of the somatic and neuromuscular responses, they are rarely included in the classification of learned responses. They require opportunity for experience and, as soon as experienced, are learned—that is, accepted by the organism for repetition.

It is responses that involve the mind and emotions that are highly modifiable and hence considered as learned responses. There is opportunity for choice in the response, and the chosen response is the learned response. The borderline is not sharply drawn since many reflexes are neuromuscular in character, and much neuromuscular learning is initiated at the cortical level.

The primary method by which the infant learns binocular control is through the experience of diplopia. The desire for a clear single image is innate, the dislike of diplopia is equally instinctive. The infant responds in various ways to his binocular stimuli, discards the responses that give him diplopia, and accepts the satisfactory responses that give him single vision. In this essentially simple manner he learns binocular skill.

So far as is known at present, there are only four ways in which a single image can be achieved: (1) By normal fusion of the images from the two eyes, (2) by using only one eye at a time (the other eye may be amblyopic, or it may be suppressed), (3) by developing anomalous correspondence, and

(4) by the Swan syndrome (turning one eye so that the stimulus to vision falls on the blindspot).

The two latter methods are comparatively rare. The vast majority of abnormal adaptations to binocular vision are by suppression. Any of these adaptations mean that the infant has successfully achieved a single image; he has learned how to solve the problem of binocular vision. If there is no obstacle to the development of fusion, that will be his response but, in the presence of certain obstacles, fusion will be either difficult or impossible and he learns some other way out.

OBSTACLES TO FUSION

The commonest obstacles to fusion are amblyopia of one eye (visual acuity less than 20/70), strabismus, hypermetropia, and anisometropia. Less common causes include aniseikonia, congenital defects, whether anatomical or neural, phorias, and developments of later life such as convergence insufficiencies which lead to abandonment of binocular skills previously acquired.

Strabismus is an obstacle since the deviation of the eyes makes fusion impossible. Unless the eyes can be moved so that the images fall on the foveas, fusion is impossible. Hypermetropia is an obstacle because, in order to see clearly, the patient has to overaccommodate, which leads to overconvergence and hence to loss of fusion.

Anisometropia is an obstacle because the two eyes are so different that fusion is difficult and hence frequently abandoned by the patient. Phorias also require much adjustment which the patient may give up for the easier method of single vision by suppression. The growing infant and child thus learns to adapt to his binocular stimuli in such a way that his response is a single image.

HOW LEARNING TAKES PLACE

Five steps are necessary for each tentative response, and only the satisfactory completion of each step will lead to learning.

1. Attention

The stimulus must receive attention. The organism is constantly bombarded by stimuli both from within and without. Most of them are ignored; no learning takes place in connection with them. The organism must select the stimulus to which it will respond before a response will be made.

2. Recognition or awareness

This is a cortical and emotional factor, not necessary at the reflex level, but of the utmost importance in establishing the conditions necessary for learning. It is the place at which the organism recognizes that the stimulus to which it is attending has possibilities for response. It is the point at which a decision is made to continue with the experience and not discard it as of no interest or value.

If attention is not followed by recognition, the learning process stops at once and the individual frees himself for attention to further stimuli.

3. Response

Response inevitably follows recognition. As soon as the organism recognizes a situation it becomes necessary to make a response. The response may be positive or it may be inhibitory. Inhibition is a very important type of response. Response is the keystone in the arch of learning. As soon as a response is made, learning is on the way to achievement.

4. Satisfaction

Again emotions enter the learning process. The response inevitably results in some feeling about the situation; satisfaction or dissatisfaction. This is the point at which learning succeeds or fails. If the response is satisfying, it is accepted as learned response and is ready for repetition. If it is dissatisfying, the individual avoids repeating that response and learning is blocked.

5. Repetition

It is at this point that learning is established as part of the individual. Adequate repetition is necessary to make the same response assured. It is by means of repetition that habits are established. Habits are the result of responses repeated so often that the steps involving the emotions or intellect are by-passed in the stimulus-response sequence. They become similar to reflexes. Since binocular vision should be the normal habit of the individual, adequate repetition is necessary, whether learned normally in infancy or artificially by orthoptic training.

Orthoptic training functions by taking the patient through the five steps of the learning process in binocular vision as rapidly and efficiently as possible. It does not function in any other way. It does not do anything to the patient or his eyes; it merely offers special opportunities for him to take the steps of learning under guidance. This kind of guidance is teaching. The technician teaches; the patient learns.

Teaching consists of offering selected stimuli to the patients so that the correct response will be easy and give him the satisfaction necessary for repetition, and sufficient practice in these responses so that they become habitual.

Orthoptics is not a treatment done to the patient; it is an opportunity offered to the patient. It is subject to the limitations inherent in all opportunities; they may be accepted or rejected by the patient. They may be rejected at step one; he may fail to attend to what is going on. He may fail at step two; he may reject the situation as one he does not care to recognize or take an interest in. He may fail to get satisfaction out of the response he makes, or he may not repeat it ofen enough to establish habits. The only thing he cannot fail to do is make a response of some sort while he is in the office.

This is an important fact because, if the response he makes is not the desired one, he is actually learning something different from the intended skill. Practice in faulty responses leads to bad habits. This is the reason that poorly conducted orthoptic training is worse than no orthoptics for the patient. He

may simply get a set of experiences in doing the wrong thing.

EVALUATION OF ORTHOPTICS

Orthoptics should be evaluated for the skill with which the right opportunities are offered, the wrong ones eliminated, and by the resulting satisfaction to the patient when he makes the right responses and dissatisfaction when he makes the wrong ones. This standard reduces orthoptics to its simple essential elements.

There are many factors involved in creating the right opportunities. They form the teaching triangle of the patient and his specific problem, the facilities available for his orthoptic training, and the skill of the technician in applying the facilities to the patient.

Since learning is response to stimulus, if the patient is unable to respond to a given stimulus, no learning takes place. For this reason it is of no value to expose a patient to difficult and impossible situations.

An example of this is the patient with an amblyopic eye who is asked to fuse. If he cannot see the object presented for fixation, he cannot get a second image to fuse with the better image, and he learns nothing about fusion.

If he is partially amblyopic, and can see when the image in front of his amblyopic eye is very brightly illuminated, he may then be able to fuse, and profit by this specialized experience, but when the illumination is decreased below the threshold of his perception the learning that has taken place no longer has any stimulus to start the fusion response, and there is no opportunity to continue the practice of fusion.

Another example is the patient who cannot fix steadily with both eyes. It may be because he has a habit of alternation, and changes fixation from one eye to the other at random, suppressing the nonfixing eye. Patients with a phoria often have intermittent suppression that prevents stable binocular fixation. As long as they do not fix steadily with both eyes they cannot start to learn the advanced steps of binocular vision, and it is useless to expect them to practice vergence control or stereopsis.

Suppression is the commonest cause for failure to profit by orthoptic training. Unless the patient uses both eyes he cannot fuse or develop the other skills of binocular vision.

Orthoptic learning begins with binocular fixation, and proceeds through the subsequent steps of vergence control, accommodation-convergence control, and training of the perception of color, stereopsis, and other interpretive skills.

The learning process requires not only that the anatomic mechanism for transmitting images shall function adequately, but that the individual shall be emotionally receptive to the stimuli so that the interpretive portion of the visual act shall be completed with satisfaction. If the patient does not give attention to the stimuli, or is not aware of what he perceives, or is not satisfied with his sensations, learning stops.

Anomalous correspondence functions so as to give the patient satisfaction with his adjustment at a reflex level and is usually associated with suppression. In some cases the anomalous correspondence reflex is so firmly established that it is beyond the power of the individual to inhibit it and distressing postoperative anomalous diplopia persists, despite all efforts to develop normal fusion skills. Variations in results in attempting to correct anomalous correspondence may often be traced directly to variations in sound application of the learning factors, or in the innate teachability (adaptability) of the patient.

ESTABLISHING EMOTIONAL ATTITUDES

Learning stops when the patient decides, whether justifiably or not, that the situation is too difficult. A large part of orthoptic teaching consists, not of arranging suitable optical set-ups for binocular experience but of establishing emotional attitudes on the part of the patient so that he will take the necessary steps in learning. He cannot be

forced to learn but he can be eager to learn.

A certain amount of discipline may be important in controlling attitudes, but the difference between establishing opportunities, and securing use of the opportunities (which is learning) must be clearly understood. Any portion of the visual act which is subject to either inhibition or choice-of-responses, is subject to learning.

Inhibition is itself a choice of response, but it is classed separately because of its importance in controlling reflexes. Reflexes, which, being innate, cannot be altered, can be inhibited under certain conditions. This is why orthoptics reaches down to the very fundamentals of binocular vision in developing normal habits; the abnormal adjustments previously made by the individual must be inhibited before normal responses can be established.

Inhibition is a very difficult response to make to a reflex stimulus. Because of their innate mechanism, reflexes are very strong and prompt in their control. Moreover, inhibition cannot be forced upon an individual. It is an emotional type of response that has to be exerted from within. The desire to inhibit must precede the act of inhibition.

This inhibitory control is slow to develop in the individual; it is definitely an attribute of maturity. This is a primary reason why young children cannot change their pattern of binocular control once it is established. They are not sufficiently mature in their inhibitions to inhibit the reflex patterns they have already learned, preparatory to learning new ones.

If the extent to which normal binocular vision is a learned process is clearly understood, the process of orthoptic correlation of faulty binocular vision may be more easily analyzed.

ANATOMIC AND PHYSIOLOGIC FACTORS

Normal binocular vision depends upon the slow maturing of anatomic and physiologic components involved. The first imperfect images received by the infant require only the simplest interpretation of direction and size. He does not need to make complicated interpretation of form and color since he has not sufficiently accurate data (clear images) to work with.

There are only three kinds of errors which can be made at the reflex level (1) Errors in direction, or fixing the desired object; (2) errors in accommodation, or getting a clear image; and (3) errors in fusion, or getting a single image.

Patients may fail in one of these factors or in a combination of two or more. All the time that the growing infant and child is getting practice in establishing a clear, single image of the object fixated, he is also getting a vast amount of interpretive experience in learning about what images mean. He is also building up a body of satisfactions and dissatisfactions with his results.

If his growth processes are normal, by the time he is eight years old he has developed normal binocular vision. If, during this growth period, something interferes with his ability to fixate, to accommodate, or to fuse his two images, he will develop an abnormal adjustment to binocular vision.

Due to his anatomic and physiologic immaturity during this period, such adjustment is reflex in character, with all the reflex attributes of becoming the innate responses, of by-passing the cortical-willed impulses, and of not being subject to further choice and change.

The fundamental reason that the patient makes such faulty adjustments is because of the comfort or satisfaction that results from them. Thus the emotion of satisfaction is the tool with which the child works to establish his visual habits. These emotions of satisfaction are even more innate than normal visual reflexes. The comfort of clear single vision will be achieved by abnormal reflexes when necessary.

The visual mechanism is such that it is possible for the patient to get comfort and satisfaction in several different ways. He is not limited to the normal way, by fusion. If

the condition which prevented the patient from developing normal fusion persists, he is as well adjusted as it is possible for him to be when he uses one of the alternative solutions of binocular vision, suppression, anomalous correspondence, or the Swan syndrome.

If, however, the original cause is corrected, as by refraction or surgery, then his original adaptation is no longer necessary. If the correction takes place while he is still young enough to be developing and experimenting with binocular vision, he has a good chance of accepting normal fusion but, if he has fully established his reflex adjustment in an abnormal manner, he will continue to use these reflexes and fail to take advantage of improved binocular opportunity. The mere presence of improved opportunity is no guarantee that the patient will use it.

The factors which control the learning process are the ones which will determine the use the patient will make of his opportunity, and the emotions are a predominant factor in the learning process.

PROGRESS IN ORTHOPTICS

It is the function of orthoptics to guide the patient through the steps of learning binocular vision. To find out whether it will correct a given problem—that is, develop normal binocular vision for a specific patient —it is necessary to know how fully such a patient meets the requirements of the learning process.

This is the science of prognosis in orthoptics, still one of the most uncertain fields in the orthoptic procedure. It need be uncertain only to the extent that the learning factors cannot be determined. The more such factors can be evaluated as part of the original diagnosis the more certain prognosis becomes. Many of the factors are discoverable only by a trial period. This is why orthoptics is so largely empirical. It is gradually becoming less so as the learning process is more completely understood and fully applied.

There are four obstacles to satisfactory

binocular learning. One has already been discussed; the patient who cannot fuse, who has an insuperable obstacle to normal binocular vision. There is still some uncertainty about what constitutes an insuperable obstacle, and more orthoptic research will be needed before such patients can be diagnosed conclusively. This applies especially to the "neuro" portion of neuromuscular disturbances, to patients in whom the etiology of strabismus is "unknown."

The second obstacle is the patient who does not accept the necessary steps in the learning process, who fails to give attention, to recognize the orthoptic situation, and to get satisfaction out of binocular effort. The most usual cause of failure in this group is immaturity. They may be immature due to calendar age, or for other reasons. Many adults do not take a mature attitude toward their visual problems.

The third group of patients fail because the fusion problem, while not insuperable, is too difficult for habitual use. This includes patients with insufficient surgical correction, and some of the phoria cases. It also includes some cases of anomalous correspondence. These patients are often able to learn orthoptic skill, but are unable to apply it continuously for casual seeing.

The final obstacle to orthoptic success consists of inability to learn to recognize the difference between single vision by fusion and by the previously developed reflex adjustment. Many cases of exotropia fall into this classification. They are characterized by inability to perceive diplopia when fusion fails.

All orthoptic failures fall into one of these four groups. Orthoptic progress is largely concerned with group two; the better the teaching skill the fewer failures in learning. The other groups are inevitably mostly the responsibility of the ophthalmologist who must improve his preparation of the patient for binocular vision to the limits of ophthalmic knowledge by removing all possible obstacles and making fusion easier.

Art of Orthoptic Teaching

The foundation of learning is the satisfaction resulting from a specific response to stimulus. This is why the orthoptic situation must center around the individual. No matter how scientifically sound the optical arrangements for binocular vision may be, if they do not result in satisfaction for the patient they will not result in learning. They will not meet his needs if they are beyond his capacity at either the physical or emotional level. He must be able to respond physically and to get satisfaction emotionally out of the response.

The primary response is simultaneous perception—the use of both eyes; the primary satisfaction is a clear single image.

When, by using both eyes, the patient gets a clear single image he has taken the first step toward establishing fusion as his response to binocular vision. Because of the fact that he is a patient, and not a normal individual, if he uses both eyes he will probably get either diplopia or a blurred image.

The art of orthoptic teaching is to give the patient sufficient satisfaction with his preliminary binocular experiences so that he will continue making new responses and not give up and fall back on his old reflexes.

All satisfactions may be grouped into two classes, physical and social. Orthoptics is obliged to make much use of social satisfactions to stimulate learning, since much orthoptic learning is far from physically pleasing to the individual. Hence it is easy to see that, if the patient is too young, or otherwise not amenable to social satisfactions, orthoptic learning will not be satisfactory.

There are many levels of satisfaction. A child may "hate" his orthoptic lesson, but if he hates the attitudes of his parents or technician when he has a poor lesson even more, the outcome will be satisfaction with a lesson well done. The manipulation of the lesson situation in such a way that the satisfactions for work well done outbalance the dissatisfactions of tedium, physical unpleasantness (such as diplopia), and the discipline

of inhibition is the basis of orthoptic teaching skill. The ability of the teacher to impart enthusiasm to the patient is part of good teaching.

The second corner of the teaching triangle is the selection of equipment and the creation of situations in which the correct response will be made by the patient. These are the facilities of orthoptic environment, which make binocular vision possible as it has not been possible before in the history of the patient.

It was the development of orthoptic equipment which was the first great forward step in the history of orthoptics. Failure to realize that exposure to such opportunity by means of this equipment was not the final step but only the preliminary step to binocular vision retarded orthoptic development by many years.

Nevertheless, the importance of adequate equipment is very great. At the present stage of orthoptic technique, it is still essential. Good equipment makes efficient teaching possible. Poor equipment need not prevent all efforts at orthoptic education, but it makes it unnecessarily tedious and difficult.

The technician herself is the corner that closes the teaching triangle. Her skill in adapting situations and creating attitudes is what determines how successfully the learning process will take place. The selection and application of equipment and facilities to each patient, day by day, and minute by minute, at each step in his binocular reëducation is the responsibility of the technician. It is the art of teaching. Orthoptic speed and success depend upon her ability in this field.

Summary

Binocular vision is a learned process. The mechanism for achieving it is preformed and the correct reflexes are innate. In the normal child, the development of the correct adjustments for normal fusion takes place during the first six years of growth. If some abnormality interferes with normal binocular vision 1 of 4 abnormal adjustments will be

learned instead; suppression, anomalous correspondence, the blindspot syndrome, or abandonment of single vision. This last adjustment is, of course, diplopia, rarely adopted by the child, but more frequently by the adult. If such abnormal learning takes place when the individual is sufficiently immature, it becomes the reflex adjustment of that individual.

Reflexes take precedence over other types of response, and cannot be altered, but can be inhibited. If the original need for an abnormal adjustment is corrected, the patient can learn normal responses.

There are four causes for orthoptic failure: an insuperable ophthalmological problem, failure to accept the learning process, lack of fusion comfort, and inability to recognize fusion errors.

Opportunity to learn does not necessarily result in learning. All the factors for learning must be present in order that learning will take place; attention, recognition, response, satisfaction, and repetition. Emotions, especially satisfaction, play a large part in the learning process.

Unless an orthoptic situation is created in which all the factors in learning are present in the right manner at the right time, binocular vision will not develop efficiently.

DISCUSSION

PETER C. KRONFELD
Chicago, Illinois

I am well aware of the fact that I am very poorly qualified to discuss Miss Lancaster's paper. One obvious reason is that I have had very little practical experience in the administration of fusion training. Another reason is that during the last few years I was engaged in a type of work in which I had to concentrate on the detection of cases of partial or complete failure of fusion training.

In 1944, I was appointed a member of a committee of the National Research Council that was to concern itself with medical problems in civilian aviation. The Civil Aeronautics Administration requested this committee specifically to include in the examinations of the applicants for pilots' licenses some test that would permit the distinction between genuinely normal binocular systems and systems that might be called patched-up ones, patched up either by surgery or surgery plus fusion training. The Civil Aeronautics Administration did not intend to bar such patched-up systems but wanted to have such systems detected and properly recorded, so as to determine whether the flying ability of the bearer of such a system differs demonstrably from that of genuinely normal systems.

At first I did not think that there was such a test that could reliably be administered by physicians without special training in ophthalmic examinations but, after extensive trials and errors, I became convinced that a modified Howard-Dolman test served the purpose of screening out inferior binocular systems very well.

In the course of this work, a great many cases of failures of fusion training have come to my attention. Nevertheless, I have tried to maintain an unbiased attitude for which I have been repaid by discovering a few cases which, as a result of fusion training, attained the highest degree of binocular coöperation, namely, an acuity of binocular depth perception of the same magnitude as that of a genuinely normal system.

Miss Lancaster's paper deals specifically with the psychology of the process of learning in orthoptics. She describes five essential

steps in the learning process—attention, awareness, response, satisfaction, and repetition. These steps seem significant and real, not only to the professional educator but also to the ophthalmologist and physiologist.

Following the terms introduced by the school of Pavlov, we often use the term "reward" instead of satisfaction. A number of years ago, I was engaged in trying to acquire a specific binocular skill, that of pseudoscopy. As you all know, pseudoscopy consists of the reversal of stereopsis by offering to a normal binocular system the "wrong" image of a three-dimensional object. A pyramid or a cube, photographed with a stereo-camera may serve as such an object. The two images are then offered to the "wrong" eye, fusion being obtained either by crossing one's visual lines in front of the images or by special pseudoscopic devices.

Such reversed images of simple three-dimensional objects very promptly and instantaneously produce the reversal of the depth effect, that is concavity, where there actually is convexity and vice versa.

If the viewed object, however, is well known to the observer, his empirical knowledge hinders the reversal of stereopsis. The stronger these empirical factors are, the more difficult it becomes to perceive reversed stereopsis. By systematic training, however, one can learn to free oneself of these empirical factors and to perceive the reversed stereopsis readily and instantaneously, despite the presence of strong empirical factors.

I subjected myself to such fusion training and, recalling my subjective sensations during that training, can very readily recognize the five steps in the training discussed by Miss Lancaster.

There are two statements in Miss Lancaster's paper that I would like to stress specifically. She advises us to distinguish carefully between fusion failure due to lack of opportunity, and fusion failure due to a specific fusion inability. I believe that this is a very important distinction.

The busy ophthalmologist in an office full of urgent major pathologic problems, is especially apt to forget that, in the case of a system with one "weaker" and one "stronger" eye, it is important to choose for the fusion test a pattern, the important parts of which can be readily perceived by the weak eye.

Most ordinary cards or slides designed for fusion tests are too difficult for an optically or perceptually inferior eye, and it is very often because of that inferiority that no fusion occurs, the examinee simply not seeing the important elements of one half of the test card. If the essential parts of the pattern offered to the weaker eye are of sufficient magnitude and impressiveness, in many such cases a true act of fusion can be demonstrated.

In her summary, Miss Lancaster states "that binocular vision is a learned process; the mechanism for achieving it is preformed and the correcting reflexes are innate."

This may seem like a radical departure from Hering's classical view of the purely innate character of binocular depth perception due to horizontal disparity. Having been an ardent admirer and follower of Hering all my life, I believe that if he could have witnessed the recent developments in our knowledge of binocular sensory coöperation, he would have worded his concept of binocular coöperation very similar to the way in which Miss Lancaster has done.

NOTES, CASES, INSTRUMENTS

ECTOPIC LACRIMAL PUNCTA

A CONGENITAL ANOMALY ASSOCIATED WITH ABSENCE OF THE LACRIMAL PAPILLAE AND CAUSING CHRONIC TEARING

ARTHUR H. KEENEY, M.D.
Louisville, Kentucky

Congenital abnormalities of the lacrimal puncta and canaliculi are usually considered in any discussion of chronic tearing, but
Fig. 1 (Keeney). Ectopic, inferior lacrimal punctum. The slightly ovalized and gapping point is located on the lacrimal portion of the lid border and is directed superiorily so as not to be in contact with the lacrimal lake.

practically no mention is to be found concerning the importance of small degrees of malposition of the puncta other than in cases of ectropion. It is the purpose of this report to emphasize careful study of the location of lacrimal points and to establish ectopic puncta as a rare but occasionally seen congenital anomaly responsible for epiphora.

Development of the canaliculi and papilla in solid epithelial cells occurs at the 35- to 36-mm. stage.[7] The superior canalicular segment buds directly from the sac anlage and traces its course through the upper lid.

Less simple, however, is the development of the inferior canaliculus. This buds from the advancing upper canalicular segment rather than from the sac anlage and, in the course of its lateral growth, cuts off a medial portion of lid tissue to create the caruncle.[3,6,7]

Thus, there are more opportunities for developmental faults to occur in the lower than in the upper portions of these passages, and clinically more anomalies are found in the lower portions. Canalization of these rods of cells begins in the 35-mm. embryo and is essentially complete at the 6-cm. stage, except for the puncta which open just before the lids separate in the seventh month.

Ida Mann[5] indicates the two basic mechanisms whereby faults may arise: (1) The buried epithelial buds which trace out the canaliculi and their opening may pursue abnormal courses, or (2) the structures, originally blocked out in solid epithelium, may not canalize. Miss Mann and others* have specified that by these mechanisms there may result (a) total absence of the puncta, (b) dimplelike, imperforate puncta, (c) atresia of the puncta, (d) occlusion of the puncta with epithelial plugs, (e) elongated or slit-like puncta, (f) shallow gutter openings in the canaliculi, or (g) accessory puncta.

In addition to these anomalies should be listed ectopic puncta. A review of French, German, and English literature since 1836 reveals only four such cases reported in this country[2] and three cases reported from France.[1] Another French case reported by Lempert[4] in which he described fissurelike openings 2 and 3 mm. long located medial

---

* Blanchet, 1846; Cabannes, 1896; Nielsen, 1896; Fox, 1900; Lebeque, 1910; Lempert, 1920; Schaffer, 1921; Towne, 1943; Brooks, 1944; Hendricks, 1944.

to the usual site is only a slight variation of this anomaly incorporating also the characteristics of slitlike puncta. One additional case is reported herewith.

CASE REPORT

History. The patient, a 23-year-old white man, complained of moderate epiphora as long as he could remember. His parents state that he had "watery" eyes even in infancy. Temperature changes, wind, or excitement caused tearing onto the cheeks. There is no family history of this disorder. Gestation and birth were apparently normal. There have been no infections in or near the eyes and no previous illnesses other than the usual childhood diseases. He has had repeated lacrimal probings by other physicians in 1945 and again in 1947, but never with any improvement. He states that Bowman probes up to size 9 have often been passed.

Complete physical, ophthalmic, and rhinologic examinations were negative except for the lacrimal findings and a perforated left ear drum. Examination under magnification revealed no evidence of lacrimal papillae on the lower lids. Transition of the lid border between lacrimal and ciliary portions followed the usual configuration and there was no ectropion.

The superior canaliculi opened by normal appearing, round puncta directed posteriorly at the junction of the lacrimal and ciliary portions of the lid border. Each inferior canaliculus opened through the lid border at the junction of the middle and outer thirds of the lacrimal portion and formed an acute angle of about 15 degrees with this free border.

The puncta thus formed had no papillae, opened directly upward, and had no contact with the lacrimal lake. The puncta gapped slightly and were ovalized so as to measure about 0.3 by 0.8 mm. in size.

Irrigating solution was delivered with ease from any punctum into the nose. X-ray films taken after lipiodol installations through the lower puncta showed the remainder of the passages to be entirely normal.

Comment. The upper puncta were able to function by the normal processes of capillarity, but because the lower puncta were not directed against the bulbar conjunctiva, they were ineffective to drain the tears. Both lacrimal glands appeared somewhat smaller than usual.

The most logical explanation for this pathologic condition seems to be an aberration in the developmental course of the canalicular buds at the 34- to 35-mm. stage, whereby they open onto the lacrimal portion of the lid border, instead of continuing laterally to the usual site on the ciliary portion. The role of constricting amniotic bands, mentioned by van Duyse and van der Hoeve,[7] which might prevent lateral growth of the buds by direct pressure, remains speculative.

SUMMARY

A case of chronic tearing caused by congenitally ectopic puncta is presented. The inferior puncta are located on the lacrimal rather than the ciliary portion of the free border and are directed superiorly rather than posteriorly. Capillarity is hence impossible. The developmental mechanism is reviewed.

BILATERAL HOMONYMOUS HEMIANOPSIA CAUSED BY VASCULAR OCCLUSIVE DISEASE

JOSEPH V. M. Ross, M.D.
Berwick, Pennsylvania

In January 1943, in the *Archives of Ophthalmology* (29:92-97), was reported a case of "Bilateral thrombosis of posterior calcarine arteries with sparing of macular vision" by P. Robb McDonald of Philadelphia, in which it is mentioned that such cases are rare. The author was able to uncover only one other case in this country and that was by Dunn, in 1895. Accordingly herewith is reported a case that I believe to be similar, although the lesions, which seem to be the same in nature, probably are slightly different in location.

In Rucker's monograph prepared for the American Academy of Ophthalmology and Otolaryngology, "The Interpretation of Visual Fields," on page 14 are illustrated fields of bilateral homonymous hemianopsia due to occlusive vascular disease which are similar to those in my case, so undoubtedly other cases have been seen and not reported.

CASE REPORT

History. This patient, H. P., aged 61 years, was first seen by me on November 29, 1947, at which time he stated that he could not get around too well because of poor and restricted vision. His history was that on November 11th at 7 P.M. he developed a pain in the left side of his head and sudden loss of vision which gradually recovered. At 11 o'clock that same night, the head pain recurred, more generalized, and vision became blurred and has remained so ever since. He

had particular difficulty in seeing to the side, so that he bumped into objects, especially those on his right side. He had been weak and bedfast until a day ago. He also stated that for several years he has been under the care of the referring physician for high blood pressure and arteriosclerosis.

Neurologic examination disclosed some spatial disorientation and some personality
Fig. 1 (Ross). Field taken on November 29, 1947, with 6/1,000 white. Vision: O.U., 20/20.

changes. His general medical checkup revealed only an essential hypertension of 170/120 mm. Hg. All laboratory studies were normal as were skull X-ray studies.

Ophthalmoscopic examination revealed poor convergence. Relative visual acuity was: O.D., 20/200, 24-point type at 14 inches; O.S., 20/100, 18-point type at 14 inches; (correctible to normal for near and far). Refraction showed: O.D., +0.5D. sph. $\bigcirc$ −0.75D. cyl. ax. 100°; O.S., +0.5D. sph. $\bigcirc$ −0.75D. cyl. ax. 80°; (add: +2.25D. sph.).

Ophthalmoscopy revealed an angiosclerosis, Grade 2, O.U. The early visual fields were as in Figure 1. Later, June 21, 1948, small islands appeared up and to the left in each field as shown in Figure 2.

The patient had some spatial disorientation, not severe, and his wife stated some

personality changes, but no alexia. Optico-kinetic nystagmus was elicited with ease but there were no spontaneous nystagmus and no reading disabilities. There were two degrees of fusion but tests for stereopsis gave variable findings. The diagnosis entertained was bilateral occlusion of portions of the posterior cerebral arteries (calcarine?) and Dr. P. R. McDonald in a personal communication stated he believed this case might well fit into this category.

For discussion of the anatomy, physiology, and other interesting aspects of these cases, reference is made to Dr. McDonald's paper in which the subject is so clearly discussed. This case differs from McDonald's in that
Fig. 2 (Ross). Field taken on June 21, 1948, with 6/1,000 white. Vision in both eyes was normal for far and near.

stereopsis was variable and spatial disorientation was present for a few months with recovery at the time of the last fields on June 21, 1948. The fields showed some peripheral recovery. Admittedly, as in McDonald's case, the exact anatomic diagnosis in this case can be made only at autopsy.

321 East Front Street.

DIABETIC RETROBULBAR NEURITIS

PETER SYKOWSKI, M.D.
Schenectady, New York

Recently Walsh[1] said that he had no "useful evidence to offer on the validity of diabetic retrobulbar neuritis as a diagnosis" and suspected "that it rarely is a correct one." The basis for this was the failure of Waite and Beetham[2] to record any cases of retrobulbar neuritis in 2,000 diabetic patients.

Fuchs,[3] in 1894, mentions "cases of chronic poisoning by diabetes" as leading to retrobulbar neuritis. De Schweinitz[4] writes of diabetic amblyopia as being the only symptom of diabetes, of having a central color scotoma, and of being more apt to be found in diabetics who use tobacco freely than in those who are abstaining. Also, Berens[5] points out that, since diabetics are more susceptible to tobacco amblyopia than healthy individuals, some writers have thought that it was this association which was responsible for the signs of retrobulbar neuritis in diabetics. Berens states further, however, that well-substantiated cases have been seen in patients who were not exposed to poisoning by tobacco in any form.

Duke-Elder[6] states that, although it has not always been clear that the retrobulbar neuritis is not due to poisons such as alcohol and tobacco, so many instances have occurred wherein other poisons can be excluded that the existence of the condition as a diabetic complication must be admitted.

Traquair[7] reveals that, (1) In many of the reported cases the diabetic origin of the amblyopia is not convincingly demonstrated; (2) in cases of general disease, such as diabetes, in smokers one would be correct in most cases in attributing the amblyopia to the tobacco if the scotoma is typical and, in any case, the causation of scotoma by endogenic toxins in diabetes and other diseases, although extremely rare, must be borne in mind; (3) cases of pure diabetic toxic amblyopia have not hitherto been sufficiently closely examined in sufficient number to establish the true characters of the field changes, (4) the defect due directly to the toxins of diabetes is multiform and often pericentral and varying in shape.

REPORT OF CASES

Several cases of diabetic retrobulbar optic neuritis have been observed and are being

reported. In these, toxicity from tobacco, alcohol, teeth, sinuses, tonsils middle ear, and so forth have been definitely excluded.

Case 1. S. M., a 53-year-old woman, was seen on March 20, 1948, with a complaint that three weeks previously there occurred a gradual onset of loss of vision in both eyes. At that time a blood sugar of 262 mg./cc. was discovered and diabetic treatment instituted.

At the time of the ocular examination, the blood sugar was normal. Visual acuity with and without correction was 20/80 in the right eye and 20/100—1 in the left eye. Fundus examination except for slight A.V. compression was normal. The tangent-screen visual field showed enlarged cecal areas, and with a 1-mm. white test object pericentral scotomas, one degree in circumference in the right eye and two degrees in the left eye.

Case 2. H. E. a woman, aged 62 years, was seen on June 4, 1948. Six months previously, a blood sugar of 450 mg./cc. was registered, at which time there was marked "smokiness" of vision. The blood sugar was normal at the time of the examination.

Visual acuity without correction in the right eye was 20/200 and, with correction, 20/70; in the left eye, 20/100—1 and 20/60, respectively. The fundus showed a few scattered retinal hemorrhages, the maculas being clear. The tangent-screen field showed, in the right eye, a slightly enlarged cecal area and with a 2-mm. white test object a 4-degree pericentral scotoma; in the left eye a slightly enlarged cecal area and a 1-degree pericentral scotoma with a 2-mm. white test object.

Case 3. B. W., a 47-year-old woman, was seen on April 4, 1948, in the hospital complaining of blurring of vision. Blood sugar was 385 mg./cc. One week later when the ophthalmic examination was performed, the blood sugar was 180 mg./cc.

Vision with and without correction was 20/30 in the right eye and 20/40 in the left eye. Except for several pin-point retinal hemorrhages, elsewhere than in the macular area, the fundi were normal. Fields revealed enlarged cecal areas in both eyes, and with a 1-mm. white test object pericentral scotomas in both eyes, one degree in the right eye and three degrees in the left eye.

DISCUSSION

That diabetic retrobulbar optic neuritis exists would seem to be unquestionable. Several such cases are presented; in these, other toxic elements, both endogenous and exogenous, have been eliminated.

Regarding diabetes, certain deplorable facts exist. For one, not all ophthalmic textbooks list diabetes as an etiologic factor. Secondly, referral of diabetics with early visual symptoms to an ophthalmologist occurs infrequently; there seems to be still an adherence to the old axiom of delaying until the general condition improves before an ophthalmic consultation is requested. It is likely that for the latter reason the incidence of diabetic retrobulbar neuritis lacks prominence.

Walsh[8] states that "obviously a fact of great clinical importance is that, if a patient complains of blurring of vision of recent onset, which is corrected by a change in lenses, the possibility of diabetes mellitus being causative should come to mind." Likewise, a case of blurring of vision in a diabetic should suggest retrobulbar optic neuritis.

CONCLUSION

The occurrence of diabetic retrobulbar optic neuritis as a clinical entity should not be questioned.

A NEW HAND-SLITLAMP*

EMANUEL KRIMSKY, M.D.
Brooklyn, New York

This new slitlamp is similar in principle to units previously reported by me.† It is not designed to replace my previous models but to show individual structural and optical features. These are: first (1) The use of a simple pencil flashlight type of battery holder to provide a flexible grasp in manipulating and in rotating the slitbeam; (2) a selective interchange of either batteries or house current with rheostat control; and (3) an improved lens-cap unit to provide a more intense and satisfactory slitbeam.

Optically, this unit consists of a straight filament lamp similar to the one used on a streak retinoscope, except that the dome of the filament was made rectangular instead of arch-shaped. Over this is fitted a condensing system consisting of a pair of plano-convex lenses, each of 11-mm. focal length. These lenses are arranged in series fashion so that the convex surface of one lens faces the plano surface of the other, and are separated by an air space amounting to

as little as 0.6 mm. The combined focal length of this condenser lens system is 5.9 mm. This lens arrangement has proved more satisfactory than the simple hemispheric condenser employed in a previous model because it provides a brighter and more clean-cut slitbeam. The slitbeam represents the image on cross section of the top of this filament when brought to the focus or conjugate focus of this condenser lens system (fig. 1).

Structurally, the lamp portion of this unit consists of a tubular battery-type handle on which is fitted a specially designed housing to hold a miniature lamp surrounded by a
Fig. 1 (Krimsky). Optical bases for slitbeam.
Fig. 2 (Krimsky). Hand-slitlamp disassembled to show component parts.

rotating cylindrical collar. The bulb remains fixed, whereas rotation of the collar through a helical arrangement draws it away from the handle without disturbing the fixed position of the bulb. The condenser lens cap housing fits snugly over this rotating collar so that both components rotate as a single unit. Such rotation serves to move the condenser lens system away from or toward the bulb which remains fixed during said operation. By greater separation of condenser and bulb, the size of the slitbeam becomes shorter and narrower and the operating distance is likewise correspondingly reduced (fig. 2).

Inspection of the eye is obtained selectively by means of a monocular magnifying loupe with collar which slides over the tubular handle. Also, one may operate this lighting system independently at any angle with the aid of a Beebe loupe or other type of magnifying lens system. The lens bracket is so designed and angulated that at the focal length of the viewing lens, the slitbeam is found to be in focus as well as in the center of the viewing field.

The slitbeam can be rotated to provide a vertical, an oblique, or a horizontal beam merely by rotating the lamp housing in this supporting lens bracket collar. By rotation of the lamp collar the slitbeam can be transformed to a broad or almost circular area of light. The supporting lens bracket has a spliced collar which fits over the battery holder, and can be thereby be easily slipped off and transferred to any type of flashlight holder using 915 AA small-type Eveready batteries. While the bracket here shown provides for a fixed angle between lens and light, I am having constructed a flexible bracket which will enable ready adjustment to variable angles between lens and light source.

745 Eastern Parkway (13).

HERPES ZOSTER OPHTHALMICUS

INITIATED BY KERATITIS

MARK THUMIM, M.D.
Middletown, Connecticut

This case is reported because of the rarity of the order in which the lesions appeared. Edgerton* could find only six cases in the literature in which the keratitis preceded the cutaneous eruption. Most of the cases which he found were reported many years ago. There have been, as far as we could find, no cases reported since Edgerton's paper.

CASE REPORT

History. Mrs. M. P., a 47-year-old white woman, was seen on August 11, 1948, with the complaint that, three days before, her left eye had become red, and that she had itching and a scratchy feeling in it as well as much lacrimation from it.

On examination, with oblique illumination, an area of corneal infiltration was seen at the limbus from the 1- to 3- o'clock positions. On August 12th, she began to have severe pain over the left side of her forehead and on the next day a rash appeared. When she was seen on that day, she had severe pain and she had vesicles on red bases on the lateral portion of her left upper lid, at the base of the nose to the left of the midline, and over the left part of the forehead. Corneal infiltration was still present.

She was seen again on August 18th, at which time no change was noted except that the left upper lid was swollen. On August 23rd, the pain was much relieved; the vesicles had dried; there was no change in the cornea.

On September 18th, the cornea was examined with a slitlamp and two areas of infiltration were seen. One of these was kidney-shaped and at the location of the infiltration originally noted. It was composed

of discrete opaque dots in the stroma. A second similar lesion, round, was just medial and caudad to the first. The vesicles had dried up and had been replaced by pitted areas in the skin.

COMMENT

This case is reported because of the extreme rarity in which the keratitis appears before the neuralgia or the vesicles in herpes zoster ophthalmicus. In this case the eye symptoms were present for four days before the true nature of the disease was evident. This is in contrast to the usual picture of this disease in which the neuralgia is followed by the skin vesiculation and which in turn is followed by eye symptoms and signs.

Professional Building.

THE POSSIBLE OCCURRENCE OF BACTERIUM ANITRATUM IN SEVERAL CASES OF CONJUNCTIVITIS*

W. A. MOOR
Saint Louis, Missouri

The following note is prompted by the recent publication of the description of a bacterium isolated, in most instances, from infectious conditions of the genito-urinary tract (Schaub and Hauber, 1948[†]). This bacterium is identical with a bacillus that has been found in several severe conjunctival infections, in so far as morphologic, cultural, and colonial characteristics are concerned.

SYMPTOMS

For the past seven years an occasional conjunctivitis has been encountered that has presented some rather puzzling features. These cases (there have been 15 from which the organism has been isolated) have all started in one eye as an itching sensation and have developed over a period of 3 to 4 days

to an appearance that is quite alarming. This progress has always continued at about the same rate regardless of what form of therapy has been tried (except for three cases in which streptomycin was used).

After this initial period of about a week or a little less, the other eye has usually undergone the same course. There is usually a great deal of injection of the blood vessels in the conjunctiva, a considerable edema of both the upper and lower lids, a moderate amount of irritation (however not as much as one would expect from the appearance of the eyes).

In three cases, there has been some swelling of the preauricular glands, somewhat more pronounced on the side of the eye showing the infection first. With most of the cases there has been a watery discharge but this has not been nearly as great in volume as would be expected from the appearance. There has never been any corneal involvement of any kind and, after 2 to 3 weeks, the inflammation has gradually subsided with no apparent after-effects.

It will be noted that this description could be thought to resemble very slightly the picture of a mild attack of epidemic keratoconjunctivitis; that there is a resemblance is shown by the fact that, on two occasions, tentative diagnoses of epidemic keratoconjunctivitis were made.

CULTURES

Cultures taken from these patients have always yielded a rather scanty growth (only one case showed as many as 20 colonies) of an organism that is rather slow-growing on the plate of initial isolation and on the medium that is used for routine eye cultures (2-percent tryptose, 2-percent agar, 0.5-percent sodium chloride, 0.2-percent dextrose, and 5-percent defibrinated whole rabbit blood). Subcultures on the same medium have given very good growth.

After about 20 hours' incubation at 37°C., the colonies as first isolated are quite small (about 0.1 mm. in diameter) and of a very

light grayish or white color. After 40 hours' incubation, the colonies are usually from 0.2 to 0.3 mm. in diameter and the gray-white color is more easily determined. Smears made from the conjunctiva or from the 20-hour culture will show Gram-negative bacilli, the majority of which will be so short that they may be easily mistaken for cocci. Longer incubation and subcultures bring out the true bacillary shape.

Since 1942, we have had 1 or 2 cases each year from which this organism has been isolated. There are two exceptions to this incidence. In 1944, there were six cases. However, 4 of the 6 were patients who had been examined by the same physician using the same clinical facilities for each patient. The period over which these six cases extended was about six weeks.

These facts would seem to indicate that the organism is moderately infective and that the human incubation period is in the region of 2 to 4 weeks. That the organism is only moderately infective would seem to be indicated by the fact that, during the period under discussion, this physician had been seeing a great many patients and had been using the same facilities for each.

In 1948, there were four cases from which this organism was isolated. One of these cases was a true epidemic keratoconjunctivitis and possibly represents a mixed infection, two cases were tentatively diagnosed as epidemic keratoconjunctivitis by two different physicians but did not have corneal infiltrates, the fourth case was not diagnosed.

TREATMENT

In all four of these cases, after the organism had been identified, streptomycin was administered, and they showed almost immediate improvement. The improvement in the one case of true epidemic keratoconjunctivitis was, of course, only to the degree that resulted in the elimination of the secondary infection.

TESTS WITH STREPTOMYCIN

During 1947, after streptomycin had become readily available, the organism was isolated from a case of conjunctivitis that had been resisting treatment with both sulfathiazole and penicillin ointments. This strain was tested for in-vitro susceptibility to the routine antibiotics used in the eye clinic and was found to be resistant to 5-percent sulfathiazole ophthalmic ointment, 10-percent sodium sulfacetamide ophthalmic ointment, and calcium penicillin ophthalmic ointment (1,000 u. per gm.). It was susceptible to 100 mg. streptomycin to 1 cc. saline and 10 mg. streptomycin to 1 cc. saline.

The tests were simply to supply an indication for a possible treatment and were very crude. The organism was seeded on a plate, incubated to dry the surface, and 0.1 cc. of the agent on a cotton swab was drawn lightly over the seeded surface. The plate was then incubated overnight and observed the next morning for inhibition of growth both at the site of the streak and on the adjacent areas.

The patient from whom this strain had been isolated was treated with streptomycin (100 mg. to 1 cc. saline). Drops were instilled every three hours. Improvement was noted on the second day of treatment.

In three cases treated with streptomycin in 1948, a solution of streptomycin containing 1 mg. to 1 cc. of saline was used, and the instillations were made every two hours. Improvement was more prompt.

ANIMAL EXPERIMENTS

The strain isolated in 1947 was suspended in saline and instilled into the conjunctivas of two rabbits and one cat that were prepared for the instillations by light abrasion with sandpaper. The two rabbits showed some moderate inflammation which started on the fourth day, lasted for about four days before it began to clear, and continued uneventfully for another two days. After this time, no signs of any kind could be seen. The cat showed nothing. The organism was not recovered from any of the animals.

It is hoped that serologic comparison with Bacterium anitratum will be possible.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY
FOR CLINICAL
OPHTHALMOLOGY

January 3, 1949

DR. BENJAMIN ESTERMAN, *president*

RECENT DEVELOPMENTS IN TONOMETRY

DR. ADOLPH POSNER discussed this subject during the instruction period.

ORBITAL TUMORS

DR. RAYMOND G. INGALLS said that an examination of all the orbital tumors in the Pathology Laboratory of the Institute of Ophthalmology of the Presbyterian Hospital revealed the following data.

They comprise a total of 216 tumors, divisible into 27 different groups, including specific cell-type tumors, and allied pseudotumors.

Their relative frequency is as follows: (1) angioma, 35; (2) pseudotumor (lymphogranuloma), 29; (3) lymphosarcoma, 22; (4) dermoid cyst, 20; (5) carcinoma, extension from accessory nasal sinuses, 16; (6) carcinoma, lacrimal gland, 7; (7) retinoblastoma, 12; (8) meningioma, 10; (9) melanoma, 9; (10) neurofibroma, 8; (11) carcinoma, extension from lids, 6; (12) cholesteatoma, 6; (13) rhabdomyosarcoma, 4; (14) neuroblastoma, 3; (15) carcinoma, metastatic, 3; (16) hematoma, 2; (17) myoblastoma, 2; (18) fibroma, 2; (19) osteoma, 2; (20) neurinoma, 2; (21) chondrosarcoma 1; (22) embryonal myosarcoma, 1; (23) neurosarcoma, 1; (24) leiomyosarcoma, 1; (25) lipoma, 1; (26) dermolipoma, 1; glioma (astrocytoma), 1.

The following list shows the age at onset for the youngest and oldest patients:

Angioma from birth to 65 years; pseudotumor, 9 to 74 years; lymphosarcoma, 1 to 77 years; dermoid cyst, 3 to 36 years; retinoblastoma, 2 months to 4 years; meningioma, 12 to 58 years; melanoma, 47 to 65 years; neurofibroma, 1 to 39 years; cholesteatoma, 37 to 63 years; rhabdomyosarcoma, 4 to 13 years; neuroblastoma, 8 months to 3 years; hematoma, 15 to 45 years; myoblastoma, 36 to 40 years; fibroma, 17 to 75 years; osteoma, 16 to 44 years; neurinoma, 7 to 15 years; chondrosarcoma and embryonal myosarcoma, infants; neurosarcoma, 7 years; leiomyosarcoma, 34 years; lipoma, 25 years; dermolipoma, 43 years; glioma, birth.

In the carcinoma group the following ages at onset were observed: Carcinoma, extension from accessory nasal sinuses, 50 to 70 years; carcinoma, lacrimal gland, 21 to 73 years; carcinoma, extension from lids, 58 to 77 years; and carcinoma, metastatic, 52 to 63 years.

Having established a table for age at onset, we may show the incidence of new growths for each decade: second, 12; the third, 16; fourth, 21; fifth, 28; sixth, 31; seventh, 15; and eighth, 9.

The first decade shows the following incidence: first year, 19; second, 5; third, 11; fourth, 6; fifth, 2; sixth, 2; seventh, 2; eighth, 2; and the ninth, 1.

This data may now be combined in the construction of a table of some value in differential diagnosis of tumors for each decade. For instance, we may list the tumors in the order of their relative frequency in a vertical column and then place the incidence figure of each tumor for each decade in adjacent horizontal columns. To make use of the table, we consult the decade column nearest the age of the patient and read down. For example, a patient between the ages of 40 to 50 years could have 1 of 11 different

types of orbital tumor, the possibility being angioma, 8; lymphosarcoma, 3; pseudo-tumor, 3; meningioma, 5; hematoma, 1; osteoma, mixed tumor of the lacrimal gland, 4; myoblastoma, 1; cholesteatoma, 2; derm-lipoma, melanoma, 1.

Discussion. Dr. Knapp asked whether, in the presence of orbital tumors or exophthalmus, was any glaucoma noticed.

Dr. Kestenbaum said that Dr. Ingalls did not mention mucocele of the frontal bone in his very complete and comprehensive report, probably because it is not a real tumor. Dr. Kestenbaum also said that Dr. Ingalls did not mention symmetrical and asymmetrical exophthalmos, that is the eye can also be displaced to one side or the other. He felt that Dr. Ingalls's material provided a basis for study as to whether such displacements can be used in differential diagnosis. He suggested that further study might be worthwhile.

Dr. Smith asked about the apparent predilection of these tumors to the left orbit.

Dr. Ingalls replied to Dr. Knapp that glaucoma has no relationship to tumors of the orbit except in neurofibroma with infiltration of the posterior ciliary nerves with buphthalmus. To Dr. Kestenbaum he answered that mucoceles were purposely omitted from this listing. To Dr. Smith he said that it is not known why tumors of the left orbit are more frequent. Cushing had suggested that this may be because the left carotid has a direct route to the eye.

MEASUREMENT OF RELATIVE EXOPHTHALMOS BY ROENTGENOGRAPHY

DR. BENJAMIN FRIEDMAN presented a method of measuring relative exophthalmos by means of X rays. The patient lies on the X-ray table, with eyes looking straight upward; a contact lens carrying a small lead dot is placed over each eye; the X rays are directed from the foot end of the table so that the central ray passes through the lead dots at an angle of 35 degrees with the table;

the shadows of the lead dots fall upon the film. If one eye protrudes more than the other, the dot on the relatively exophthalmic eye will be projected farther back than the dot on the less protruding eye.

The chief problem is to position the eyes in space in such a manner as to eliminate sources of error, and to permit duplication of this spatial position each time an exposure is made. Steps in the procedure designed to achieve these ends were detailed.

Film measurements are made by dropping a perpendicular from the center of each dot shadow to the proximal edge of the film. The longer perpendicular belongs to the relatively exophthalmic eye. For practical purposes the difference in the length of these perpendiculars represents the relative exophthalmos, magnified four times.

The contact glasses are standard plastic lenses, with a central lead dot 1.5 mm. in diameter. The dots are placed over the pupillary centers. The lenses are handled with the usual suction grip. No fluid is needed between cornea and lens. One drop of anesthetizing solution is sufficient.

Readings in successive examinations may vary from 0.0 to 0.5 of ocular position. This, in most cases, is less than the variations found in repeated reading with the exophthalmometer.

The method measures relative, not absolute exophthalmos. For example, if both eyes were equally exophthalmic, there would be no unequal projection of the respective shadows. No dependence is placed on the distance of cornea from orbital margin. Horizontal as well as anterior deviations may be recorded.

Dr. Friedman concluded that this method cannot be expected to supplant instrumental exophthalmometry but it offers additional information. The two methods should supplement and check each other.

Discussion. Dr. Saskin asked how a norm is established.

Dr. Esterman said that, since the patient's

head is kept constant, it might be of help to place a lead dot on the brow, to give the increase of the exophthalmos on subsequent examinations.

Dr. Kestenbaum said that Dr. Friedman was using a new principle in exophthalmometry, since he uses the position of the entire head or, to be more exact, the position of the occiput and the two ear ducts as points of reference. Hertel's exophthalmometry measures the position of the cornea in relation to the two lateral orbital margins; Kestenbaum's ruler-exophthalmometry uses the two superior orbital margins as points of reference. Each of these methods is based on a different principle. The use of all three methods and comparison of the results may make us more independent of the individual variations.

Dr. Friedman replied to Dr. Saskin, that there is no need to establish a norm since each patient is his own norm. To Dr. Esterman, he replied that the lead dot was a good idea, and that he had used it. Dr. Friedman said that it acted as a center pivot from which the lateral displacement of the eyes can be measured. To Dr. Kesterbaum, he answered that any method to determine exophthalmos requires determination of what plane is to be used for measurement. In this case the plane cutting through the auditory canals is used. Overdevelopment of one part of the head can be determined by clinical examination, which should supplement the X-ray findings.

ANGIOGRAPHIC DIAGNOSIS OF ORBITAL TUMORS

DR. ANTONIO GRINO presented a paper on this subject, which was published in full in the AMERICAN JOURNAL OF OPHHTALMOLOGY, volume 32, page 897, July, 1949 (with Dr. Edwin Billet).

Discussion. Dr. Samuel Gartner said that this is an important presentation as it gives us a splendid additional technique for the study and diagnosis of orbital tumors. This is a puzzling group of diseases and we certainly need more help in their diagnosis. Exact localization in the orbit is important since a decision can then be made whether the ophthalmologist should remove the growth by the orbital route or whether a neurosurgeon should operate by the transfrontal approach.

Dr. Knapp said that he believed that the ophthalmic surgeon could deal with most cases of orbital tumor. He asked why, in the first cases presented, X-ray therapy was preferred instead of surgery.

Dr. Kestenbaum said that he had seen the first of the cases presented by Dr. Grino several years ago and again about one year ago. The latter examination revealed, in addition to the severe exophthalmos, damage to the central vision and a definite temporal hemianopic defect in the visual field of the right eye. Although the exophthalmos indicated a space-taking process in the orbit, the temporal hemianopic defect hinted at a lesion in the chiasmal region, therefore in the middle fossa of the skull.

At the Montefiore Hospital an angiography was done which demonstrated the presence of an angioma in the orbit. A renewed examination of the angiogram revealed the additional presence of an angioma in the middle fossa. This additional finding made the clinical and angiographic findings congruent.

Dr. Rizzuti asked whether stereoscopic X-ray examination was done.

Dr. Billet replied to Dr. Knapp's question, that X-ray therapy was tried first and, if it was not successful, surgery was then used. However, in this particular case X-ray therapy was very successful.

Dr. Grino replied to Dr. Rizzuti that stereoscopic X-ray examination is done routinely in all cases of this type.

Bernard Kronenberg,
Recording Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

November 15, 1948

DR. A. C. KRAUSE, *president*

(Presented by the Department of Ophthalmology, University of Chicago)

CLINICAL MEETING

SJØGREN'S SYNDROME

DR. T. W. ANDERSON said that D. G., a 48-year-old white woman, was first seen at the University of Chicago Eye Clinic in August, 1948. She complained of episodes of burning and reddening of the eyes for the past 25 years. This had become worse during the past four years and constant during the past year. The eyes felt dry and sticky, sensitive to light, and vision was slightly hazy.

In 1940, the patient developed polyarthritis and swelling of the small joints of the hands and feet. In 1942, she had an episode of girdle pain lasting eight months, and lost 40 pounds. At that time an enlarged spleen was noted; there was no free acid in the gastric juice. She had been slightly anemic since the age of 15 years, for which she had taken liver and iron.

About this time she developed "chronic sinusitis" with postnasal drip. A turbinectomy had been done 22 years ago to help relieve the chronic episodes of conjunctivitis. In 1942 all the teeth were removed because of their poor condition; they had always been chalky. In 1946 she developed a salivary calculus of the right parotid duct followed by infection which drained externally below the right ear. Her mouth had been dry for 10 years and was now more so. In the same year a right mastoidectomy was performed. She developed thrombophlebitis in the lower extremities at this time.

Since adolescence she had had attacks of left pleurisy and, in 1947, a severe attack, of unknown etiology, developed; chest X rays at this time were reported normal. An infection of the left parotid gland, with associated skin infection of the face, was treated with streptomycin. Cultures of the conjunctivas, nose, and throat have revealed streptococcus; bacterial vaccines have given no relief. Local medication to the eyes has given only temporary relief at times.

The patient is a gaunt, slender woman who appears chronically ill. The skin is thin and atrophic, with brown patches on the lower extremities. There is generalized atrophy of the mucous membranes of the nose and throat, dryness, hyperemia, and patchy membrane. A thick mucoid substance was expressed from the sublingual salivary duct. The left parotid gland was enlarged, nontender, with a fibrous consistency. There were scars under the right ear and over the right mastoid. The mandible was slightly limited in action, with a dry clicking sound.

Eye examination revealed vision to be: R.E., and L.E., 20/30 with a 1-mm. pinhole. The skin of the lids was atrophic and dilated vessels were visible near the margins. The palpebral conjunctivas were injected and thickened; the bulbar conjunctiva was moderately injected, with slight superficial flush at the limbus. There was a thick ropy discharge in the lower fornix. The anterior surface of the corneas had patches of adherent thick mucoid material. There was central heavy punctate staining of the epithelium with 2-percent fluorescein and the epithelium was thinned and granular appearing. There were eight filaments standing by one end from the anterior surface of the right cornea. The Schirmer test was 0 mm.

On general physical examination the liver was lightly tender and enlarged two fingers below the costal margin. The spleen was very tender and enlarged four fingers below the costal margin. There was swelling of the wrist joints and fusiform swelling of the metacarpal and metatarsal joints, and some limited motion of the elbow joints. All laboratory tests were within normal limits with the exception that histamine gastric analysis

showed no free acid and scanty secretion; culture of the conjunctivas showed Hemolytic staphylococcus and C. xerosis.

This patient will be hospitalized for further study. At this time, the clinical impression is that she has keratoconjunctivitis sicca, syndrome of Sjøgren.

HEALED LUETIC NEURORETINITIS PAPULOSA

DR. PAUL G. WOLFF said that this woman, aged 28 years, came to the clinic in October, 1946, with the complaint of poor vision in the right eye of one year's duration. One year before she had suddenly developed severe parietal headache, a generalized measlelike rash including the soles and palms, broad streaklike flashes of light, and a veil in front of the right eye. Her physician at that time told her she had secondary syphilis. Several weeks later the symptoms spontaneously subsided.

When first seen, vision was: R.E. 15/200 and could not be improved; L.E., 20/20+4, uncorrected. The optic disc of the right eye showed mild temporal pallor and an inferior temporal, dense, largely avascular connective-tissue proliferation. This tissue extended forward into the vitreous and was anchored to large retinal veins and several old chorioretinitic lesions. Peripheral fields were constricted. The left eye was normal.

The patient is still receiving antisyphilitic therapy and the Wassermann test is now negative. The eye status is the same.

This condition was first adequately described in 1926 by A. Fuchs, although previous accounts of the disease are mentioned in the literature.

SCIENTIFIC MEETING

DR. DOUGLAS BUCHANAN spoke on "Neurologic manifestations with optic-nerve atrophy in children."

DR. PAUL C. BUCY spoke on "Neurologic manifestations with optic-nerve atrophy in adults."

Richard C. Gamble,
Secretary.

OPHTHALMIC MINIATURE

Kepler's overwhelming astronomic· discoveries overshadow his important contributions to our understanding of the process of seeing. He was a strange, erratic genius and his was a most unusual mind. In the discovery of the laws of the solar system an essential step was the emancipation from mechanical models. Kepler did not proceed by thinking out possible devices by which planets might be moved across the sky. He was guided by a sense of mathematical form, an aesthetic instinct for the fitness of things. In these later days it seems less incongruous that a planet should be guided by the condition of keeping the action a minimum than that it should be pulled and pushed by concrete agencies. Many of his contemporaries must have frowned on these rash adventures of scientific thought and felt unable to accept the new kind of law without any explanation or model to show how it could possibly be worked.

After Kepler came Newton, and gradually mechanism came into predominance again. It is only in the last years that we have gone back to something like Kepler's outlook, so that the music of the spheres is no longer drowned by the roar of machinery.

A. S. Eddington in *Naturwissenschaft,* November 14, 1930

THE ACADEMY MEETING

The 54th annual session of the American Academy of Ophthalmology and Otolaryngology was held in the Palmer House, Chicago, October 9 to 14. It was one of the most successful meetings from many points of view.

The presence of Sir Stewart Duke-Elder, the guest of honor, was one of the chief attractions. He has won the hearts of his American colleagues by his scientific attainments and his many noteworthy contributions to our science. His textbook is a priceless heritage to present and future generations of English-speaking ophthalmologists everywhere. He has endeared himself to each of us by his open-handed friendship, sincerity, and great personal charm. His appearance at the meeting assured a happy and cheerful atmosphere which permeated all of the activities and dispelled for a little while the gloom of world troubles and the depression that accompanies the thought of socialized medicine.

As is usual, the multiple activities of the Academy occupied every single working hour, beginning early in the morning and extending far into the night. As one of our

witty members remarked, "the Academy meeting makes you take nembutal to sleep and benzedrine to stay awake."

The total registration topped all records; 4,848 members and guests arrived early and most of them stayed to the last minute of the last day. One-hundred-eighteen individual courses (including 12 home-study course discussion periods) and 30 continuous courses in ophthalmology, with a faculty of 175 instructors, totalling 376 hours of instruction, were eagerly attended. It would seem that every possible subject in ophthalmology was covered, with the heaviest interest and attendance in those subjects that offered clinical aids to the practicing physician. Nearly every course was sold out and the popular ones were packed to the doors.

Thirteen out of the 23 scientific exhibits were of ophthalmic interest and all were of high caliber. The exhibit, "Primary chorioretinal aberrations with night blindness," by Harold F. Falls, in collaboration with P. J. Leinfelder, David G. Cogan, Frank D. Carroll, and F. Bruce Fralick, justly received the first award; "Malignant melanoma of the uveal tract," exhibited by Helenor Campbell Wilder of the Armed Forces Institute of Pathology, with the collaboration of Lawrence P. Ambrogi, won the second award; and that of Samuel Gartner, with the collaboration of Abraham Schlossman and Edwin Billet, on "Ocular pathology in general medicine," was awarded the third ribbon. Many fruitful hours of study of these and the other exhibits amply repaid the keenly interested members and guests.

At the joint session of the scientific sections, the president, Conrad Berens of New York, spoke on "Research in otolaryngology and ophthalmology; The role of the American Academy of Ophthalmology and Otolaryngology." He pointed out the support that the academy has given to pertinent research in the past and emphasized its future influence in this field of activity. His figures showing that for every 70 dollars spent for the care of the blind, one dollar was spent

for ophthalmic research and the prevention of blindness, were startling and depressing. He urged the formation of an international institute for the prevention of blindness and the conservation of sight, whose purpose would be to coördinate the efforts of the many organizations that are dedicated to saving sight. It would be most effective if established near the permanent headquarters of the United Nations in New York City.

Sir Stewart's address was on "The physiology of the intraocular fluids and its clinical significance." He summarized the present state of our knowledge of the subject to which he has contributed so much from his own researches in the past. His fluent style, his genius for collecting the essential facts, and his masterly presentation made a most difficult subject sound easy. He quoted Goethe to the effect that "hypotheses are cradle songs which lull to sleep" and added his own thought that, while this may be true, "if you sleep perchance you dream and may even awake to write a sonnet."

He then went on to develop a working hypothesis of the subject of the formation and disposal of the intraocular fluids so logically that time and future investigation will surely bear it out.

The remainder of the scientific papers were of remarkably high quality. The annual Edward Jackson Memorial Lecture was given by William L. Benedict of Rochester, Minnesota. His subject was "Diseases of the orbit." As is customary, the lecture will be printed in the JOURNAL and each reader will have the pleasure of appreciating its excellence.

The various ophthalmic symposiums, that are becoming the most important and attractive features of the scientific sessions, were unusually good. Space does not permit a detailed description and analysis of these symposiums, but it might be mentioned that the papers by John M. Sheldon, Ann Arbor, Michigan, on the "Immunologic aspects of allergy"; the entire symposium on "Primary chorioretinal aberrations with night blind-

ness," by the groups whose exhibit on the subject won the first prize previously mentioned, and the attractive discussion of it by Sir Stewart, who pointed out that, after listening to the papers, one can readily see that the biogenic stimulator treatment of retinitis pigmentosa is "no good"; and the thrilling and outstanding contribution of Albert B. Sabin of Cincinnati to the symposium on toxoplasmosis, appeared to excite the admiration and sustained applause of the members more than has ever been experienced before in any scientific session of the academy.

A feature, introduced at the last meeting, of beginning each session with a short clinicopathologic case report by an ophthalmic pathologist, is of such value and interest that it undoubtedly will become permanent. The case report by J. Clement McCulloch on the pathology of choroideremia was particularly worthy of attention. It disposes once and for all the controversy over whether or not atrophy of the choroid is actually present in this condition.

Among the remaining papers on the program, all of merit, that of Alan C. Woods on the "Use of antibiotics and sulfones in clinical ocular tuberculosis" was preëminent. One of our many guests from all over the world at the meeting, Dr. T. a'B. Travers of Melbourne, Australia, presented an important paper on the "Practical importance of abnormal retinal correspondence," and pointed out the value of operation in this condition as early as it can be recognized.

As is customary, motion pictures of ophthalmic surgery by various surgeons were interspersed here and there in the program and were excellently received.

The social aspects of the meetings likewise were a bit overwhelming. The event of primary interest was, of course, the banquet. It was so well attended that the members, their wives, and guests, overflowed onto the large balcony surrounding the ballroom, an unheard of proceeding. After the award of 14 honor keys, Sir Stewart spoke, at the top of his form, of the machinations of socialized medicine in Great Britain in such a way that even the discussion of this gloomy and unhappy subject could not dissipate the rosy aura of good fellowship and pleasure that surrounded the dinner party. At the conclusion of the dinner, Sir Stewart was awarded the plaque of the academy, signifying his honorary membership in the organization.

The hospital reunion dinners, all crowded, occupied the attention of the members, as is usual, on one of the evenings. A dinner for the exmedical officers stationed in the E.T.O. was obviously enjoyed and was graced by the presence of the erstwhile Brigadier Sir Stewart, a former comrade in arms to all of those present.

The smoker on another evening was so crowded that the floor space became smaller and smaller as new tables were added, thus increasing the pleasurable crowding together of the dancing couples. Before and after these and other events, one·kept himself busy scurrying about from one cocktail party to another, in a sort of academy pub crawl.

The incoming president of the academy is J. Mackenzie Brown of Los Angeles, California. The following officers were elected: 1st vice-president, Edwin B. Dunphy of Boston, Massachusetts; 2nd vice-president, Kenneth L. Craft of Indianapolis, Indiana; 3rd vice-president, James Mason Baird of Atlanta, Georgia. Derrick Vail of Chicago was chosen president elect.

Derrick Vail.

RECOMMENDATIONS FOR PROTECTION OF PATIENT IN CONTACT-LENS FITTING

Under the heading "The contact lens problem," Conrad Berens, secretary of the American Committee on Optics and Visual Physiology, has written an article published in the *Journal of the American Medical Association* (*140*: 602-603, June 18, 1949), in which he discusses the fitting of contact lenses and

the recommendations made by the Committee on Optics, primarily for the protection of patients who desire contact glasses or for whom contact glasses are thought by their refractionists to be desirable.

The idea of lenses that can be worn in contact with the eyeball and the under surfaces of the lids is an old one. Dr. Berens states that it was first suggested by Sir John F. W. Herschel, a British astronomer, in 1827, and that, in the latter part of the 19th century, wearable lenses were made for pathologic conditions. In recent years much more satisfactory contact lenses have been manufactured and new modifications are continually being brought forward.

The Committee on Optics and Visual Physiology sent a questionnaire to 2,000 certified specialists of the American Board of Ophthalmology, asking their experience with contact lenses. Of 413 replying who had had experience with contact lenses, 373 preferred the molded plastic technique. The consensus was that the fitting of contact lenses was not without danger to the patient and should be performed by, or under the direct supervision of, an ophthalmologist. Corneal abrasions and corneal ulcers have resulted from the fitting and at least one case of a lost eye has been recorded.

The commonest motivation for the purchase of contact lenses is undoubtedly vanity, particularly the desire of young women with high myopia to be able to see clearly without glasses. There are, however, occupations, such as acting, dancing, war-time flying, in which the usual glasses are a serious handicap and contact lenses may be of immeasurable help. Ophthalmologists will invariably state that the great field for contact glasses is that of keratoconus. Fortunately, however, these cases are rare. Human nature being what it is, vanity will continue to influence many and the demand for contact glasses will not only continue, but will increase.

Ophthalmologists consider the fitting of contact glasses, especially the molded type in which anesthetizing drops are necessary, to be a medical procedure. Therefore, the American Committee on Optics and Visual Physiology, after a careful study of the situation in this country, has made the following recommendations which have been endorsed by the four national societies having representatives on this committee:

1. National and local ophthalmologic societies should regulate the prescribing of contact lenses and the dissemination to the public of information regarding contact lenses.

2. The prescribing and/or the fitting of contact lenses by persons not properly licensed under state or national laws should be prohibited.

3. Medical opinion should be obtained in every case before contact lenses are prescribed.

4. Ophthalmologists should establish standards for approving the qualifications of technicians who wish to engage in fitting contact lenses.

5. Competent impartial research should be initiated toward the solution of unsolved problems concerning contact lenses. The main problem at the present time, provided that the fitting of the lenses is correct, is that of hazy or cloudy vision. Blurring of vision occurs inevitably after wearing a contact lens for some hours because of the altered metabolism of the cornea.

6. The public should be warned against those who advertise the superiority of their services or of any particular type of contact lenses. It should be pointed out that the public should not patronize such advertisers because competent professional practitioners do not resort to commercial advertising.

Some of these recommendations are deserving of special comment. Recommendation 1 would require legislative action. The mere fact that ophthalmologists may consider that the prescribing of these lenses and the dissemination to the public of information on this subject should be regulated by ophthalmological societies will not necessarily bring this about. These activities will surely

not be so confined if manufacturers and dispensers of optical goods who deal directly with the public are not legally disbarred from performing these functions. In this, as in most health matters, states are essentially autonomous and there are 48 of them so that it is always difficult to pass restricting legislation, particularly if strongly opposed. Such objection would be made especially by those who advocate and dispense contact glasses that can be fitted without anesthetics, such as small corneal discs or any other form that does not require molding.

Recommendation 2 implies that the prescribing and fitting of contact lenses should be treated as a specific activity and provides that only a well-defined group be permitted to perform this function. If new legislation were to be sought, this paragraph would have to be a part of it and would encounter opposition similar to that in Recommendation 1.

Recommendation 3 emphasized the ophthalmological opinion that fitting contact glasses is a medical problem, but does not specify that medical opinion must be obtained.

Recommendation 4 would place the certificating of technicians under the control of ophthalmologists, and put the burden of determining minimum standards for technicians on the doctors.

Recommendation 5 encourages further studies for improving contact glasses.

Recommendation 6 is an application of that part of Recommendation 1 referring to the dissemination to the public of information about contact lenses and their fitting.

In summary, the committee believes that control of the prescribing and fitting of contact glasses should be in the hands of physicians and that such laws as are necessary to accomplish this should be passed. This, as stated, is a large order, but suitable procedures should be initiated to bring these laws into being. This will require much effort on the part of many ophthalmologists.

It may be that most good will be accomplished by educating the public and utilizing to the full such existing laws as apply to this problem. New legislation, as pointed out, will surely be extremely difficult to pass and, if passed, to enforce. Existing laws generally prohibit the use of drugs by others than medical doctors. In the meantime, these laws should be strictly enforced. In the case of fitting contact glasses, it is not unusual for the technician to state that the physician has delegated to him or her the right to use drugs. No physician should ever assume such a power. He certainly does not have it legally and, since it is he that is legally responsible for any injury to his patient, he not only is acting illegally, but foolishly.

Generalizing further, these recommendations of the American Committee on Optics and Visual Physiology seem excellent suggestions for regulating the prescribing and fitting of contact glasses. If their intent is carefully followed, there should be a minimum of danger to the patient and there is a good possibility of continuing improvement in the construction of these lenses through well-directed research.

Lawrence T. Post.

ERRATUM

In our article in the AMERICAN JOURNAL OF OPHTHALMOLOGY, (32: 247, Part II, June, 1949), the first two columns of the Table 6 were incorrect (due to an error in the manuscript) and should read as follows:

Major Semiaxis (a in mm.)	Minor Semiaxis (b in mm.)
0.0346	0.00289
0.0316	0.00316
0.0283	0.00354
0.0224	0.00448
0.0173	0.00577
0.0141	0.00707
0.0130	0.00769
0.0100	0.0100

Only with these figures will the cross-sectional areas of the elliptical tubes be equal

while having largely different pressure drops.

Cincinnati, Ohio.

CORRESPONDENCE

NATIONAL FOUNDATION
FOR EYE RESEARCH

Editor,
American Journal of Ophthalmology:

An organization known as the National Foundation for Eye Research,* founded in Washington, D.C., proposes to raise funds for ophthalmic research. This foundation hopes to encourage public support for medical research aimed at discovering the causes for ocular diseases leading to blindness and at developing more efficacious therapies.

The National Foundation for Eye Research will differ in its operation from many organizations designed to further medical research in that its funds will not be restricted to the study of any one disease but will be used to promote research in the whole field of ophthalmic diseases.

The activities of the foundation will be limited entirely to supporting and establishing research centers for ophthalmology in various localities, leaving other approaches to the prevention of blindness and rehabilitation of the blind to existing agencies.

The need for an expanded research program is apparent when one considers that there are about 260,000 blind persons in the United States with 20,000 new cases added annually, and that the existing funds, facilities, and personnel available for ophthalmic research are pitifully inadequate to study thoroughly the basic causes of the diseases which result in blindness. For instance, there is less than $400,000 spent annually in the United States on medical research primarily designed to decrease the number of blind— less than 1 percent of that used for rehabilitation of those who have already lost their sight. Moreover, there are only about a dozen

* Shoreham Building, Washington, D.C.

trained, full-time research men working in this field in the whole country, and few practicing ophthalmologists can devote a significant amount of time to research because of the restrictions of an active practice.

Mr. George Swartz, well known for his promotion of other medical philanthropies, has been selected as national chairman. With the assistance of a board of directors composed of prominent laymen, he will be responsible for the activities related to raising the necessary funds. The allocation of funds for research purposes will be made upon the advice of a scientific advisory board consisting of Dr. V. Everett Kinsey, chairman; Dr. Francis Heed Adler, Dr. Edwin B. Dunphy, Dr. Jonas Friedenwald, and Dr. Alan C. Woods.

It is hoped that ophthalmologists through their contact with the public will add their support to the group of laymen whose interest in expanding ophthalmic research has led to the formation of the National Foundation for Eye Research.

(Signed) Edwin B. Dunphy,
Boston, Massachusetts.

NATIONAL OPHTHALMOLOGICAL SOCIETY

Editor,
American Journal of Ophthalmology:

For some years past, Dr. Louis Bothman had been discussing the matter of the organization of a national ophthalmological society which would be truly representative of the ophthalmologists of the country.

There are other organizations in ophthalmology such as the Section on Ophthalmology in the A.M.A., and the Academy, which is eye, ear, nose, and throat, and the Association for Research. However, it would seem that a national ophthalmological society, in the same sense that such a professional and scientific organization exists in other fields, one that is truly representative of the best in ophthalmology, could materially help in raising the standards of ophthalmology in the teaching, clinical, and research fields.

It might be possible for such a society to undertake annual lectureships of outstanding quality as a regular part of its program, as well as the publication of an eye journal restricted purely to original contributions. Certainly there is room for such a publication in view of the length of time it takes for articles to be published at the present time.

As a personal friend of Dr. Bothman's for more than 20 years, I should like to help make his dream of such an organization become a reality.

(Signed) Samuel V. Abraham,
Los Angeles, California.

description of aniseikonia and of contact lenses.

As is characteristic of all of Sir Stewart's work, this book is written in an extremely clear and straightforward style. It is most difficult to find any fault with the factual material. Since there is a legitimate difference of opinion regarding the best method of refraction, especially as relates to the use of cycloplegics, many will not agree with the emphasis on the manifest refraction in young adults and early presbyopes but the views expressed are conservative and represent the practices in many offices and clinics.

William A. Mann.

BOOK REVIEWS

REFRACTIONS. By Sir Stewart Duke-Elder. St. Louis, The C. V. Mosby Company, 1949. Price, $6.25.

The fifth edition of Duke-Elder's well-known textbook on refraction retains all the features which have made it one of the most popular authorities in the field and, at the same time, presents new and enlarged sections that bring the entire work up to the most modern conceptions. The introductory chapter, dealing with the philosophy of the symptoms and treatment of eyestrain, is particularly commendable for its effort to evaluate the relation of symptoms to errors of refraction. It is rightly emphasized that many errors do not require correction but that, when they do, accuracy is essential.

The discussion of the principles of physiologic optics as applied to the eye is naturally much more brief than that contained in larger works or in Duke-Elder's monumental *Textbook of Ophthalmology* but it would seem quite adequate for the purpose. Recent views on the biologic determination of myopia are discussed and material on transient changes in refraction is presented. New or amplified passages deal with anomalies of convergence, the streak retinoscope, relanoskiascopy, the mechanism of accommodation, and the effectivity and equivalence of lenses. Particularly notable is the amplified

DIE KLINIK DER LABYRINTHITIS UND PARA-LABYRINTHITIS AUF GRUND DES RÖNT-GENBEFUNDES. By Prof. Dr. Med. Horst Wullstein. Stuttgart, Georg Thieme Verlag, 1948. Imported by Grune & Stratton, New York. 150 pages, 64 figures, bibliography. Price, $8.50.

Wullstein's monograph, a culmination of 10 years of work, presents a masterly study of the labyrinth in health and disease. The exquisitely clear skiagrams, with which it is profusely illustrated, are compared with anatomic sections and artistically clarified by accompanying sketches. This volume, which should prove invaluable to the roentgenologist, otologist, and others interested in this field, reflects the best traditions of German scholarship and publishing.

James E. Lebensohn.

DERMATOLOGIE FÜR AUGENÄRZTE. By Walter Schönfeld, M.D., Professor of Dermatology of the University of Heidelberg; Director of the University Clinic of Dermatology. Stuttgart, Georg Thieme Verlag, 1947. 104 pages, illustrations, 16 color plates, and index. Price, $7.25.

The volume is well organized, and the illustrations, particularly in color, are excellent. In a general introduction, some of

the principles of diatheses are outlined. There is a brief résumé of the technique of the patch and intracutaneous tests for allergic manifestations. The chapter dealing with treatment is rather incomplete since little but modifications of zinc and mercury preparations are enumerated.

Two main chapters are devoted to the discussion of individual forms of skin afflictions. The first deals with those of an infectious nature, and is subdivided into groups of unknown origin, parasites, and fungus and bacterial infections. The second chapter discusses dermatoses, avitaminoses, malformations, congenital diseases, and tumors. In closing, anomalies of the hair, the glands of the skin, and pigmentation are described.

It should not be expected in an outline of this scope that anatomic-pathologic details would be discussed at length. However, it is disappointing that ocular changes are only mentioned rather than described in any detail. For example, the conjunctival involvement in erythema exudativum multiforme is just listed as occurring in association with the general symptoms; no details are given. Equally unsatisfactory is the discussion of Boeck's sarcoid and tularemia; syphilis is all but omitted.

Because there is a close relationship between the two specialties, this little volume is worthwhile as a refresher course in dermatology for ophthalmologists. A treatise of this nature should represent a desirable addition to the literature, and it is to be regretted that Schönfeld has accomplished this only to a limited extent.

Stefan Van Wien.

TRANSACTIONS OF THE OPHTHALMOLOGICAL SOCIETY OF PARIS (and of the Ophthalmological Societies of the East, of Lyon, and of the West). August-September, 1948, pp. 405-529; October, 1948, pp. 532-694.

The session of June 13th was opened by a famous guest speaker, D. Cordier, who discussed the role of vitamins in the physiology of vision and in the metabolism of various structures of the eye. Van Canneyt and L. DeBaets made suggestions on the marking of the cylinder axis. P. L. Drouet and C. Thomas reported a detailed biochemic and etiologic study of Sjøgren's syndrome. J. Nordman's study on the treatment of strabismus dealt especially with the timing of surgery and a comparison of early surgery, as done in the United States, with late surgery, as favored in most European countries.

Cordier reported a case of acute glaucoma after intracapsular cataract extraction. Total iridectomy controlled the tension. E. Duhamel and Umbdenstock found a reacting pupil in a case of total blindness after embolism of the central retinal artery and discussed the function and location of the optic and pupillary fibers.

Thomas, Cordier, and Algan observed a patient with tuberous sclerosis who was simultaneously affected with band-shaped keratitis, a coincidence never before described.

At the meeting of June 21st, Beauvieux read an excellent pathologic and clinical review of glaucomatous cupping which emphasized the importance of vascular disturbances and ocular hypertension. A. Mercier achieved considerable local improvement in three cases of neuroparalytic keratitis with placental implants.

Le Jamtel read a paper on lymphoblastic sarcoma of the orbit and Offret and Hervoulet saw three patients with unusual pathologic changes at the posterior pole which simulated malignant lesions and which, after enucleation, proved to be inflammatory reactions.

In the October volume, P. Toulant and A. M. Larmande described the nervous and mental disturbances of sympathetic ophthalmia, probably encephalitic and meningitic in origin. The younger patients in this group had endocrine disturbances and the older

ones a hypercholesteremia. P. Bonnet suggested that a patient with the complications of sympathetic ophthalmia should not be deprived the benefit of surgery. In his hands, an intracapsular cataract extraction was successful.

A diagnosis of bilateral tuberculous tarsitis was made by Belz and verified by biopsy. Tarsectomy and diathermy coagulation were combined with calcium therapy. He also emphasized the value of Friedenwald's ophthalmoscope in the diagnosis of central serous chorioretinitis.

P. Bonnet saw a thrombosis of the central vein, which was formed by leukocytes and an unusual segmentation of white and red blood cells in the preretinal hemorrhage, in a severe case of leukemia.

L. Paufique described a new technique for the breaking of anterior synechias before completing keratoplasty. The place of trephination is outlined with a 6-mm. trephine, overlapping the anterior synechias by 2 mm. Sutures are applied at the edge of the disc and knotted so that they are in place for the traction to be applied later on. The cornea is only partly perforated by slightly inclining the trephine. The corneal flap is carefully raised with the traction sutures and the anterior synechia is removed with an iris hook and scissors. Of 8 operations of this kind, 5 were uneventful, 1 was complicated by a mild iritis, and 2 by an increase in tension.

Alice R. Deutsch.

SITZUNGSBERICHTE DER WIENER OPHTHALMOLOGISCHEN GESELLSCHAFT. By Dr. H. Fanta. Wien, Urban & Schwarzenberg, 1947.

The proceedings of the Vienna Ophthalmological Society cover in 98 pages the 23 meetings held between January 19, 1942, and February 26, 1945. A wide range of diseases, operations, and pathologic conditions of the eye are discussed. Many of the ideas expressed are widely known now and there is very little material relating to the war. An index by subjects and authors makes any comment easily found.

J. Böck, H. Fanta, K. Heinz, J. Meller, K. Lindner, A. Pillat, and R. Rössler are prominent among the contributors.

GAIL SOPER.

IL TRACHOMA. By Giambattista Bietti. Rome, 1947. 142 pages.

In this monograph, which was contributed as part of a program financed by U.N.R.R.A. to combat social diseases, Professor Bietti systematically considers the various aspects of the trachoma problem. He presents its history, discusses etiology and epidemiology, and adequately describes the manifestations of the diseases in the various tissues that are involved, the complications, pathology, diagnosis, prognosis, prophylaxis, and treatment.

F. H. Haessler.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

1
ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Cooper S., and Daniel, P. M. **Muscle spindles in human extrinsic eye muscles.** Brain 72:1-24, Jan., 1949.

With the demonstration of neuromuscular spindles in human extraocular muscles the authors have completed the chain of evidence that establishes an anatomical basis for proprioception in ocular motility. The orbital contents were removed soon after death in 60 individuals ranging in age from 82 years to newborn. The individual extrinsic eye muscles were dissected out, pinned on cork, and fixed in 10-percent formol-saline. The muscle spindle consisted typically of a group of fine cross-striated muscle fibers with a rich nerve supply in a thin torpedo-shaped capsule of fibrous tissue. The appearance is reminiscent of human fetal muscle spindles and suggests that the human eye muscle spindle may be a rather primitive form of this neuromuscular organ. The muscle spindles were found in the proximal third and at the proximal end of the distal third of the muscles, but not in the belly. The largest number of muscle spindles were in the inferior rectus. Muscle spindles have also been found in the extrinsic eye muscles of the chimpanzee, in certain ungulates (goat, deer), but not in the macaque monkey, dog, cat, or rabbit. James E. Lebensohn.

Harms, J. W. **Transplantation of regenerative tissue into the anterior chamber.** Klin. Monatsbl. f. Augenh. 114:298-308, 1949.

Autoplastic experimental transplants of young regenerative tissue from the tail or an extremity of Triton alpestris into the anterior chamber led to a dissolution of the lens and, in some cases, of the retina. After resorption of the implant a new lens was formed from the upper border of the iris. Experiments with tadpoles raised in thiourea showed inhibition of the organs of internal secretion with a disturbed development of the eyes such as exophthalmus, smaller bulbi, and reduction in the number of rods and cones. Max Hirschfelder.

Moerike, K. **Comparative functional examination concerning the special thickness of the choroid in the macular region of the eye.** Klin. Monatsbl. f. Augenh. 114:308-319, 1949.

The choroid has greater thickness in the macular region. This is shown by the author's measurements on slides from human eyes. In birds with formation of two maculas in one eye like the tern, a particularly well developed stretch of choroid is found under each macula. The metabolism of the rods and cones in these regions requires a greater blood supply and the greater thickness of the underlying choroid corresponds to this requirement..(References.) Max Hirschfelder.

2
GENERAL PATHOLOGY, BACTERIOLOGY, IMMUNOLOGY

Bailliart, J. P. **The pathologic physiology of the corneal endothelium.** Ann. d'ocul. 182:509-513, July, 1949.

Corneal endothelial cells are capable of being transformed into macrophages in the aqueous humor. In the cellular examination of the aqueous large cells of approximately 50 μ. are not infrequent, with nuclei of 20 μ. and granules of 5 to 7 μ.. These cells frequently contain hematinic debris, leucocytes, iris pigment or even bacteria. The author has shown that these cells are directly derived from the corneal endothelium and considers that their phagocytic qualities are associated with senescence and inflammatory reactions.   Chas. A. Bahn.

Cogan, D. G. **Vascularization of the cornea. Its experimental induction by small lesions and a new theory of its pathogenesis.** Tr. Am. Ophth. Soc. 46: 457-471, 1948.

After small experimental lesions in the cornea of the rabbit a sequence of events leading to new bloodvessel formation occurred with remarkable regularity. After a latent period the proximal vessels, chiefly the venules and capillaries, became engorged and saccular aneurisms developed. These aneurisms burst, caused

hemorrhage into the corneal stroma and became deflated. The hemorrhagic area then became riddled with new capillaries, most of which receded in a few days, leaving loops directed toward the lesion.

Interstitial vascularization of the cornea occurs when compactness of the cornea is reduced in the region of pre-existing vessels.   David O. Harrington.

Fazakas, S. **The role of Penicillium species in fungus and bacterium cultures.** Szemészet 2:69-73, 1949.

Since 1931, the author continuously examined the fungus flora of eyes. One third of the fungi found were Penicillium species. In mixed cultures consisting of Penicillium and another species such as fission fungi, Aspergilli, Periconia keratitidis, Microsporon felineum, and Trichophyton, it was mainly the Penicillium that inhibited bacterial growth. In the mixed cultures containing Penicillium and Actinomyces the inhibiting effect was nearly equal. Many cases of symbiosis and neutrality also were observed between Penicillium and other fungi or bacteria.
                     Gyula Lugossy.

Letterer, Erich. **Ophthalmology from the viewpoint of general and experimental pathology.** Klin. Monatsbl. f. Augenh. 114:289-298, 1949.

The many and varied problems of general pathology which are illustrated by clinical or experimental findings in the eye are reviewed. Phenomena of normal and disturbed circulation can be observed at the limbus, and hemodynamic disturbances during experimental collapse in the retina. In angiospastic retinopathy, dystrophic cell damage is the result of disturbed circulation with deposit of fat and lipoids in the tissues. Storage of lipoids and phosphatids in cells is a characteristic finding in Tay-Sachs and Nieman-Pick disease. Deposit of amyloid in the ocular

tissues is rare. The avascularity of the cornea is the basis for a particular course in inflammatory processes. Hyperergic inflammatory reaction and elective sensitizing of tissues are demonstrated in interstitial keratitis as well as in sympathetic ophthalmia.   Max Hirschfelder.

Marchesani, O. **The problem of the endogenous inflammations of the eye.** Arch. f. Ophth. 149:69-94, 1949.

The frequency of keratoconjunctivitis eczematosa, endogenous uveitis and periphlebitis retinae are studied with respect to age and sex of patients afflicted with one or the other of these conditions. Keratoconjunctivitis eczematosa occurs most often in children under five years of age. Endogenous uveitis and periphlebitis retinae reach their maximums for people between 20 and 25 years of age. The keratoconjunctivitis is correlated to the so-called exudative lymphatic diathesis. Foci of lymphatic disease, especially of the glands of Waldeyer's ring of the throat, irritate the vegetative nerves of the cornea and conjunctiva and make these tissues vulnerable. A special type of endogenous uveitis is found in women during the menopause. Acute uveitis is more often seen in men, chronic uveitis somewhat more often in women. Periphlebitis prevails in young men and seems often to be combined with disturbances of the endocrine glands.   Ernst Schmerl.

Meves, H. **The elastic structure of the ocular bloodvessels.** Arch. f. Ophth. 149: 275-281, 1949.

This is a second contribution dealing with this problem. Twelve retinal gliomas were studied. In the majority of the vessels the elastica was lost. The main branches of the arteries of the glioma were often found dilated and hyperplastic. The hyperplastic parts of the bloodvessels of retinal origin showed the structural

peculiarities described before. In 8 to 12 choroidal sarcomas an elastica was present.   Ernst Schmerl.

3
VEGETATIVE PHYSIOLOGY, BIOCHEMISTRY, PHARMACOLOGY, TOXICOLOGY

Auricchio, G. **Permeability of the lenscapsule for glucose after paracentesis.** Boll. d'ocul. 28:161-168, March, 1949.

Rabbits' eyes were punctured three times at 48-hour intervals; 18 hours after the last paracentesis the animals were exsanguinated and the lenses examined. Some of the lenses were immersed in a 0.5-percent solution of glucose in 0.85-percent sodium chloride solution at 38°C. for two hours, before the glucose content of the lens was determined. The glucose content ascertained minus the glucose content of a lens just removed plus the glucose metabolized by a rabbit lens at 38°C. was assumed to equal the amount of glucose which passed through the lens capsule in the two hours. The other intact lenses were dialyzed against physiologic salt solution for two hours at 38°C.; the glucose content of the originally sugar-free salt solution was used as a measure of the permeability of the lens capsule. The left eyes of the rabbits were not punctured and their lenses served as control material. For determination of the glucose content the Weekers modification of Dumazert's technic was used. In four tables, 16 experiments are described; the calculations resulted in evidence of a decrease of permeability of the lens capsule after repeated paracentesis. (References.)   K. W. Ascher.

Duke-Elder, S., Davson, H., and Woodin, A. M. **Studies on the intraocular fluids.** Brit. J. Ophth. 33:452-454, July, 1949.

This is the third of a series of studies

injection of histomine. Vitamin B_2 (nicotinic acid) causes only a slight increase in ciliary permeability.   Vito La Rocca.

Swan, K. C. **Ocular effects of the choline esters.** Tr. Am. Ophth. Soc. 46:651-672, 1948.

A decade of experience in the ocular effects of the choline derivatives is reviewed. It is not possible as yet to evaluate the influence of these drugs on the intraocular vascular system but their effects on the muscles of the iris and ciliary body and upon intraocular pressure seem fairly well established. The question of corneal penetration and pharmacologic action of the choline esters is discussed with particular reference to their effect on intraocular pressure. The mydriatic cycloplegic action of Dibutoline and its range of clinical usefulness are discussed.
                    David O. Harrington.

4
PHYSIOLOGIC OPTICS, REFRACTION, COLOR VISION

Berens, Conrad. **The contact lens problem.** J.A.M.A. 140:602, June 18, 1949.

Considerable progress in the manufacturing and fitting of contact lenses has taken place in recent years. Nevertheless most patients can tolerate wearing the lenses for a limited time only because the solution used between the contact lens and cornea is unsatisfactory.

The American Committee on Optics and Visual Physiology recommends that the prescribing and fitting of contact lenses be restricted to properly licensed persons, that ophthalmologists establish a standard for approving the fitness of technicians, and that impartial research be initiated toward the solution of unsolved problems.   R. Grunfeld.

van Beuningen, E. G. A. **Experimental observations concerning the sensitization** of eye and ear during measurements of adaptation phenomena. Arch. f. Ophth. 149:230-239, 1949.

When the dark adaptation of several test persons was interrupted by short light stimuli, the readaptation increased in speed and intensity. Corresponding effects were observed in experiments in which the adaptation of the ear was studied. The author assumes that during the increased sensitiveness of the eye retinoneural functions prevail over photochemical processes.   Ernst Schmerl.

Cibis, P., and Huck, H. **Studies of the central color sense in normal and congenital colorblind people using stimuli of definite size and duration.** Arch. f. Ophth. 149:176-198, 1949.

The distances were determined at which the colors of small test objects on a neutral gray background were just recognized. The time was measured during which the perception of these stimuli faded. Large numbers of normal persons recognized the color of 1 by 16 mm. red and yellow objects and 1.4 by 16 mm. green and blue objects at distances of 3 m. or more. Where shorter distances were needed the color sense was doubtful or definitely pathologic. Normal persons also perceived the yellow color of test objects 5 by 5 mm. in size for a period of 2 minutes and at distances of 2 m. or more, whereas in pathologic cases the color was perceived at 1.2 m. distances or less.   Ernst Schmerl.

Cross, A. G. **Contact lenses.** Brit. J. Ophth. 33:421-445, July, 1949.

An analysis of the answers to a long, inclusive questionnaire sent to 1,850 patients who sent in 875 replies is presented. The results are most significant to all interested in the fitting and the problems of contact lenses. The most important aspect of the problem is the question of

tolerance to wear. Of those who replied to the questionnaire, one third have given up the wearing of their lenses which fact, in the light of the expense and time involved, emphasizes the great responsibility upon the fitter. The number of failures is considerably less among patients with a pathologic condition. Satisfactory fitting is still the major problem, and tolerance will increase with improvements in method.   Morris Kaplan.

Durham, D. G. **Plastic lenses in industry.** Tr. Am. Acad. Ophth. pp. 680-682, July-Aug., 1949.

The advantages of plastic lenses in industry include greater resistance to pitting from sparks of different sorts, more resistance to fogging, lightness, and greater protection. (3 figures.)

Chas. A. Bahn.

Irvine, S. R. **Amblyopia ex anopsia. Observations on retinal inhibitions, scotoma, projection, light difference discrimination and visual acuity.** Tr. Am. Ophth. Soc. 46:527-575, 1948.

This exhaustive monograph on the subject of amblyopia ex anopsia should be read in its entirety. Patients with non-paralytic strabismus fail to note apparent displacement of a fixated light during the cover test because the percipient elements of the retina that are involved because of the angle of squint have the same directional value as the macula of the fixing eye. This observation suggests that if, while one eye is fixating, prisms of varying strengths are moved before the deviating eye to displace the image less than the angle of squint, the image would not be seen or would be falsely projected. Moving prisms before an eye might be used to study projection, inhibition and scotoma in strabismus and amblyopia. Amblyopia based on organic lesions might be differentiated from amblyopia ex anopsia if

retinal inhibition and projection were more altered in amblyopia ex anopsia. The prism displacement test proved valuable in the study of retinal inhibition and projection in strabismus and amblyopia. Numerous cases were analysed singly and in groups and an attempt was made to ascertain criteria helpful in prognosticating return of vision in the amblyopic eye of an adult after loss of the other eye.

David O. Harrington

Ludvigh, E. J. **Visual acuity while one is viewing a moving object.** Arch. Ophth. 42:14-22, July, 1949.

Foveal visual acuity while one is viewing a moving object has received curiously little attention. The only reference to this subject is a note by Langmuir, who, in an effort to estimate the speed of a deer botfly, whirled above his head a piece of solder fastened to a string and noted at what speed the piece of solder appeared blurred. In view of the absence of any information, this subject was investigated.

Visual acuity was determined while the test object viewed appeared to move circularly in a plane perpendicular to the line of sight. The diameter of the circle and the velocity of the test object were varied. It is shown that when the eye is following such a moving object, acuity is reduced by reason either of the inability of the eye to move sufficiently rapidly or of the inability of the subject to adjust the relative innervation to the various ocular muscles sufficiently rapidly, or of both. It is shown that in following a moving object the extrafoveal position of the image is a negligible factor in producing the observed reduction of acuity. It is probable that imperfect pursuit movements, although maintaining the image in the immediate vicinity of the fovea, nevertheless result in a motion of the image on the retina which reduces visual acuity because the retina has less inten-

sity contrast. The hypothesis is confirmed by showing that increased illumination of the moving test object increases visual acuity. Ralph W. Danielson.

McDonald, P. R. **Evaluation of night vision.** Tr. Am. Ophth. Soc. 46:576-607, 1948.

In the experiments reported the tenfold variation in the final rod threshold of healthy young adults confirms the findings of other investigators. Two different night vision tests employed have shown good reproducibility. It has also been shown that the visual threshold in normal persons is not improved with large doses of vitamin A. Given a good instrument and an interested examiner, a test of night vision becomes an important diagnostic aid as well as a means of demonstrating the important aspects of scotopic vision. David O. Harrington.

Pacalin, G. **Physiologic diplopia in depth perception.** Ann. d'ocul. 182:617-635, Aug., 1949.

Depth perception fundamentally involves the mobility of accommodation and convergence as well as the coordination of binocular muscle balance, visual acuity and memory. Slight physiologic diplopia favors the perception of depth. Objects viewed at a closer distance than the fixation point cause crossed diplopia, and objects viewed at a greater distance than the fixation point cause homonymous diplopia. Two groups of figures are presented to illustrate that slight variations of accommodation and convergence change the apparent relative distances of objects from each other. These figures consist essentially of two larger circles with smaller eccentric circles arranged at less than the interpupillary distance. The cube of Necker is also employed to illustrate that the impression of a third dimension on the printed page is an optical illusion.

The impression is produced through perspective and memory interpretation. The author believes that these fundamentals are important in the phorias and tropias. In the former, the process is reversible. Chas. A. Bahn.

Sauter, H. **A modification of telescopic spectacles by the use of contact glasses.** Arch. f. Ophth. 149:142-155, 1949.

Contact lenses serve as oculars of these optical systems. The author considers magnification, size of the visual field and brightness of the image. Reference is made to a similar study by Bettman and McNair (Am. J. Ophth. 22:27, 1939). Ernst Schmerl.

Thomson, L. C. **Photopic luminosity curve and visual purple.** Brit. J. Ophth. 33:505-508, Aug., 1949.

The author reports his investigation of the photopic luminosity curve. The contribution of the color-perceiving mechanism to the sensitivity of the light-adapted eye is represented. Maximum sensitivity is found in the spectral regions in which modulator activity is most marked. An attempt can be made to separate the activity of the brightness mechanism from that of the color-perceiving mechanisms in the human eye. Orwyn H. Ellis.

DIAGNOSIS AND THERAPY

Dansey-Browning, C. **On the use of amniotic membrane.** Brit. J. Ophth. 33:-518-520, Aug., 1949.

Amniotic membrane was used to replace a defect left by the excision of a large benign melanoma of the conjunctiva. The eye healed rapidly and almost without reaction. Orwyn H. Ellis.

Eröss, S. **Therapy of scleritis.** Szemészet 2:74-76, 1949.

The etiology of scleritis is not uniform.

However, signs of oversensitivity can be found in all patterns. Therefore, the capacity of the organism to react should be transformed lest the process prove resistant to causal therapy. To this end, the author applied a specific stimulant therapy. Changes in the blood count and the sedimentation rate showed that paragen produced an adequate transformation of reactive capacity. Gyula Lugossy.

Guyton, J. S. Enucleation and allied procedures. A review and description of a new operation. Tr. Am. Ophth. Soc. 46: 472-527, 1948.

The history and technic of extirpation, enucleation and evisceration of the eyeball with or without implants is thoroughly reviewed. Ruedemann's introduction of semiburied plastic eye implants and Cutler's use of a separate attachable prosthetic section initiated technics which usually result in normal appearance and motility of artificial eyes. Infection, extrusion, or reduced motility with the semiburied implants may be potential late complications. A procedure involving the use of an exoplant with which there is no contact of inert material with any tissue except epithelium introduces a new principle which may reduce late complications. David O. Harrington.

Harms, H. Fundamentals, methods and meaning of pupillary perimetry for the physiology and pathology of the visual organ. Arch. f. Ophth. 149:1-68, 1949.

A complete study of the functions of a retinal area requires the determination of its light sense, its visual acuity, its color sense and its pupillomotor excitability. The present study compares perimetrically and under definite conditions light sense and pupillomotor excitability of the various retinal areas. A special instrument and threshold stimuli are used. The blind spot can be demonstrated by pupil-

lary perimetry. Marked differences of pupillomotor excitability in normal persons are noticed. With dark adaptation the light sense shows a central scotoma while the pupillomotor excitability of the central fovea is at its maximum. Homonymous defects of the visual fields are paralleled by pupillomotor disturbances. Changes of the pupillomotor excitability are also found with foci proximally to the lateral geniculate bodies.

Ernst Schmerl.

Koch, H. Contribution to the treatment of psychogenic amauroses. Arch. f. Ophth. 149:282-287, 1949.

In 9 cases of psychogenic amaurosis, electro-shock treatment or nitrous oxide narcosis was followed by definite improvement, Ernst Schmerl.

MacLean, A. L. Surgical procedures in retinal vascular disease. Tr. Am. Ophth. Soc. 46:348-366, 1948.

Perforating scleral diathery with aspiration of the subretinal fluid is a safe and effective procedure in the treatment of serous retinal detachment complicating diabetic retinopathy. A glass applicator with broad concave tip is used and controlled negative pressure is supplied by an electric suction pump. The procedure is safe if the scleral opening is not too large or if the retinal opening has been sealed off by previous diathermy treatment. Cervical sympathectomy was used effectively in the treatment in one case of bilateral occlusion of the central retinal artery. David O. Harrington.

Schuessler, W. W., and Steffanoff, D. N. Dermal grafts for correction of facial defects. (A series of 80 cases.) Plastic and Reconstr. Surg. 4:341-351, July, 1949.

Dermal grafts, free of subcutaneous fat, are used in various areas of the body for "fill-in material." Absorption of the der-

mal grafts show a decrease from the original volume of approximately 15 percent. A short history of the use of dermal grafts is given. This material should be used wherever there is a deficiency in the contour of the face, nose or forehead with normal skin to overlie it and a good vascular bed beneath it. It should not be used where firm structure is required, such as for protection of the brain tissue. It has the advantage over the cartilaginous graft of being soft and pliable, abundant and easy to remove and insert in the recipient area, and it seems much better than free fat-fascia graft. Various methods of obtaining dermal grafts are mentioned, and the author recommends the split-split method, introduced by Zintel. A full-thickness graft is removed with the dermatome, the dermatome reset and the desired thickness of epidermis recut on the dermatome. Sometimes the derma is inserted as a strip, or it may be cut in sections and packed up in the form of a pyramid. In 80 cases complications were present in 7.5 percent, of these 1.2 percent were due to infection, and 1.25 percent to cyst formation. Nine photographs and one drawing show this material used for repair of the atrophy of the retrotarsal fold after enucleation, for the adherent scars which form after severe trauma to the infraorbital rim, and for other regions of the face and nose.

Alston Callahan.

6
OCULAR MOTILITY

McLean, J. M. **Direct surgery of paretic oblique muscles.** Arch. Ophth. 42:50-65, July, 1949.

The author discusses seven years' experience with direct surgery of the underacting superior oblique muscle and of the weak inferior oblique muscle. There appears to be no way by which to judge

the amount of surgical correction required better than that of adjusting the tension according to the surgeon's sense of touch. The reasons for direct operative procedures to strengthen a weak oblique muscle are cited. Technics for tucking a paretic superior oblique and advancing a paretic inferior oblique muscle are described. Illustrative cases are reported. The methods of judging the amount of operation to be performed are discussed.

Ralph W. Danielson.

Murray, W. B. **A review of trachoma.** Canad. M.A.J. 60:574-580, June, 1949.

The author gives a comprehensive review of the history, etiology, differential diagnosis, pathology and treatment of trachoma and stresses the fact that early diagnosis is important for the prevention of the spread of this mildly contagious disease. The modern treatment of trachoma is efficient. The incidence of trachoma among the Indians has been reduced from 26 to 3 percent within four years after the introduction of the new treatment by the U.S. Indian Service

R. Grunfeld.

Rubino, A., and Bassi, I. **Concomitant squint and status dysraphicus.** Giorn. ital. oftal. 1:404-417, Sept.-Oct., 1948.

In a large number of patients with strabismus, the authors found a facial asymmetry very frequently. In the belief that facial asymmetry is a sign of status dysraphicus, they looked for other signs of this anomaly and found them in a large number of cases.

Vito La Rocca.

Scobee, G. **Intermittent exotropia.** Tr. Am. Acad. Ophth. pp. 658-673, July-Aug., 1949.

Anatomic abnormalities are the major factor in its causation. Complete cure is

usually possible surgically. Variations depend on mechanical obstacles to convergence, voluntary and involuntary convergence, and the strength of the fusion mechanism. Abnormalities of the intermuscular membranes, check ligaments, foot plate and other anomalies of insertion are the principal anatomic conditions involved. Exotropia is frequently greater at 20 feet than at 13 inches, unless occlusion or voluntary convergence relaxation is employed. The convergence near point is often practically normal. Generally speaking, intermittent exotropia or exophoria of 18 degrees or more can be cured only surgically. The author advocates bilateral external rectus recession performed at one time. Phorias require as much surgical correction as tropias. In the treatment of nonsurgical cases the pin-to-nose convergence exercise may decide the justification of further orthoptic training. Twenty-five cases, in 11 of which there were vertical deviations, are reported and analyzed.   Chas. A. Bahn.

Stanworth, A. **The final results of squint operations in which restoration of binocular single vision was not expected.** Brit. J. Ophth. 33:477-484, Aug., 1949.

The author presents a detailed study of the final binocular coordination in a group of patients in whom binocular single vision was not expected. In all it was concluded before surgery that orthoptic training would be unsuccessful, or it was tried and abandoned. The results showed that of the 26 percent that improved, 20 percent developed stereoscopic vision. Of the patients without binocular vision, 9 percent improved and of these 7 percent developed stereoscopic vision. Of those with simultaneous macular perception, 17 percent improved and 13 percent developed stereoscopic vision. The data suggest that if fusion will result it will

do so within 12 months after operation. Patients with vision approximately equal in the two eyes tend to develop stereoscopic vision more readily than those with unequal vision. The size of the angle of deviation before operation appeared to be of little significance. An early onset of the squint usually precludes the attainment of good binocular vision. The alternating type has less chance of improvement than the unilateral type. There was apparently no optimum relationship of age to the time of operation. The postoperative angle of squint was most important. Of the patients with simultaneous perception and a deviation of five degrees or less after operation, 49 percent developed fusion, whereas only 11 percent of those with more than five degrees of deviation developed fusion. When there was no binocular vision but the deviation was less than five degrees, 22 percent of the patients developed stereoscopic vision and when the deviation was greater, only 4 percent developed fusion. Wright, E. S. **Extraocular muscle paralysis from spinal injection of pantopaque.** California Med. 71:214-215, Sept., 1949.

A case report of external rectus muscle paralysis which developed five days after the spinal injection of pantopaque is presented. Three months later spontaneous recovery occurred with normal motility.   Orwyn H. Ellis.

7

CONJUNCTIVA, CORNEA, SCLERA

Bietti, G. **Antibiotic therapy of virus diseases of the eye.** Ophthalmologica 118:101-114, Aug., 1949.

Bietti and his associates have found penicillin, streptomycin and tyrothricin to be ineffective in keratitis due to herpes simplex and in epidemic keratoconjuncti-

vitis. In trachoma, however, the author reports definite, favorable response to frequent local applications of penicillin in concentrated aqueous solutions or ointments. Within a few days the secondary bacterial invaders as well as the inclusion and initial bodies disappear and the clinical picture improves correspondingly. The deeper tissue changes due to trachoma respond better to sulfonamides than to penicillin. Streptomycin and tyrothricin are ineffective in trachoma. The author considers the inclusion and initial bodies as the visible, corpuscular form of the virus. In contradistinction to its definite effect upon the trachoma virus penicillin does not alter the course of inclusion conjunctivitis. In one case of the latter disease the author observed rapid recovery under local streptomycin treatment. An extensive review of the literature is included.   Peter C. Kronfeld.

Boase, A. J. **Eyelash in the lacrimal punctum.** Brit. J. Ophth. 33:513, Aug., 1949.

A patient presented himself for treatment of an irritated right eye in 1944, and again for treatment of an irritated left eye in 1949. Each time there was an eyelash in the punctum and the root end protruded. Ulcer and granulation developed in the conjuntiva whereas keratinization is the expected change. Perhaps the rough root of the lash is more dangerous.
                                    Orwyn H. Ellis.

Buecklers, M. **A new familiar type of corneal dystrophy.** Klin. Monatsbl. f. Augenh. 114:386-397, 1949.

A complicated type of corneal dystrophy is described. The first signs appear during the childhood. There are severe defects of the epithelium with attacks of pain and inflammatory symptoms. The attacks stop after puberty and begin anew

two decades later. At times there are corneal opacities without pain. The dystrophy involves the epithelium and, especially, Bowman's membrane. The mode of inheritance seems to be dominant. (1 family tree, 10 figures, references.)
                                    Max Hirschfelder.

Cass, E. E. **Interstitial keratitis occuring in a case of Reiter's disease.** Brit. J. Ophth. 33:454-455, July, 1949.

A case of Reiter's disease in a young man who also had severe interstitial keratitis combined with keratitis profunda and iritis in both eyes is reported. The disease progressed in severity despite all treatment and vision was reduced to the counting of fingers.   Morris Kaplan.

Cima, V. **Explanation of unusual reactions after transplantation of cadaver conjunctiva.** Boll. d'ocul. 28:155-160, March, 1949.

Conjunctiva from the cadaver was first used for transplantation by Rosenzweig in 1939. In the Sassari and Pavia Eye Clinics, Bietti used this method repeatedly, preserving the cadaver conjunctiva for as short a time as possible in Ringer's solution with 5,000 units of penicillin per cc. The results were satisfactory but not better than autotransplantation of mucous membrane. In two cases of severe recurrent pterygium, however, marked reactions were observed and ascribed to tissue immunity reactions. (References.)
                                    K. W. Ascher.

Cogan, D. G. **Nonsyphilitic interstitial keratitis with vestibuloauditory symptoms.** Arch. Ophth. 42:42-49, July, 1949.

Four additional cases of the previously-described syndrome of nonsyphilitic interstitial keratitis with vestibuloauditory symptoms are reported. The interstitial keratitis was bilateral in three of the new

cases and unilateral in one. It was characterized by patchy, granular infiltrates in the deep stroma, which varied from day to day, unaccompanied by any conspicuous intraocular reaction. The vestibuloauditory symptoms were similar to those occurring in Ménière's disease and were followed by pratically complete deafness in three of the patients. The ocular and vestibuloauditory symptoms appeared within a few days in three patients but were separated by a five month interval in one. Again all four patients were young adults, all had a leukocytosis, and one a significant eosinophilia.

Ralph W. Danielson.

Coppez, L. **Partial lamellar keratoplasty.** Ann. d'ocul. 182:597-604, Aug., 1949.

This type of operation should be more extensively used because it affords better vision in eyes not adapted to total keratoplasty. Among its advantages are more rapid recovery and better nutrition of the graft, as well as its simple technique and the infrequency of surgical complications. The author reports nine cases in detail with illustrations which show the regularity of the reflecting surface of the cornea after operation. The Franceschetti technique is used. Chas. A. Bahn.

Corrado, A., and Toselli, C. **Hereditary luetic parenchymatous keratitis.** Rassegna ital. d'ottal. 18:97-111, March-April, 1949.

Eighty percent or more of luetic keratitis was found to be hereditary. Trauma was an unimportant cause in the development of the lesion. The authors studied 106 cases of the disease and have tabulated many data. Sixty-seven percent of the cases developed the keratitis under 20 years of age and 66 percent of all patients were females. The serologic tests were positive in all but four cases. Complications, such as posterior synechiae, dense corneal opacities and irregular astigmatism were more frequent when the disease appeared first in later life.

Das Gupta, B. K., and Usman, M. **Bilateral symmetrical tuberculous ulcers of the bulbar conjunctiva treated with streptomycin.** Brit. J. Ophth. 33:501-505, Aug., 1949.

Bilateral tuberculous ulcer of the bulbar conjunctiva did not respond to ordinary therapy but healed promptly when streptomycin drops of high concentration were used. Acid-fast bacilli were found in the scrapings. (4 figures in color.) Orwyn H. Ellis.

ten Doesschate, J., and Fischer, F. P. **Some statistical observations on the frequency of occurrence of pterygium and pinguecula in relation to age.** Ophthalmologica 118:137-142, Aug., 1949.

The incidence of pinguecula as a function of age is expressed by an S-shaped curve which rises very slowly up to the age of 15 years. There the curve makes a sharp bend and starts to rise steeply up to the age of 50 years, where it begins to taper off. Plotted on log-log paper the incidence of pinguecula becomes a linear function of the subject's age. The incidence of pterygium follows a similar pattern but all frequencies are considerably lower than those of pinguecula. The hypothesis is offered that the persons liable to develop pterygium form a distinct group of the population. In this group also, the relationship of the incidence of the disease to age is expressed by a similar S-shaped curve.

Drescher, E. P., and Henderson, J. W.

Senile hyaline scleral plaques. Proc. Stf. Mtgs. Mayo Clin. 24 :334-336, June 8, 1949.

Three cases of senile hyaline plaques are reported from the Mayo Clinic to clarify the diagnosis of this condition. The usual location, the clinical appearance, and the pathology are described.

Donald T. Hughson.

McGavic, J. S. Surgical treatment of recurrent pterygia. Tr. Am. Ophth. Soc. 46 :608-632, 1948.

An operative technic is described for the eradication of severe recurrent pterigium. The results were good in a series of 38 cases in which other procedures had failed to prevent recurrences. The procedure consists of lamellar peratectomy, submucous resection of all scar tissue, recession of the conjunctiva by suturing it to the sclera proper at least 5 mm. from the corneoscleral junction and allowing the denuded cornea and sclera to become epithelized. Beta radiation is used postoperatively when necessary to control vascularization. The technique is also suitable for pseudopterigia, epibulbar tumors, repair of symblepharon and removal of superficially vascularized scars. The literature is reviewed. (References.)

David Harrington.

Rosen, E. The importance of the cornea in virus diseases. Ophthalmologica 118: 81-101, Aug., 1949.

The pathogenesis of corneal lesions in systemic virus infections is discussed in the light of the newer concepts concerning the antigen-antibody relationships in such diseases. Typical clinical cases are reported to illustrate the author's views. The difference in response between the avascular center and highly vascular periphery of the cornea is stressed.

Rubino, A., and Simonelli, M. Thymus radiation for the treatment of vernal catarrh. Giorn. ital. oftal. 1 :453-455, Sept.- Oct., 1948.

The thymus was irradiated with X rays in 15 patients, 8 to 20 years of age, with vernal catarrh, without any noticeable improvement. The findings are in contrast with those of Stanhope, who believed that the hypertrophy of the thymus was a fundamental element in pathogenesis of vernal catarrh.

Vito La Rocca.

Taussig, J. Epithelioma of the cornea following a cement burn. South African M. J. 23 :383-384, May 14, 1949.

A 35-year-old man injured his left eye with particles of cement. A slight burn of the bulbar conjunctiva and tarsus of the left eye ensued. Two years later a small tumor developed at the limbus and spread toward the pupil. The adjacent conjunctiva was injected in pterygium-like fashion and scattered through it were discrete, pinhead-sized, wart-like tumors. Two fragments of tissue were removed. One fragment consisted of simple pigmented squamous papilloma overlying a single mucous gland, the other showed squamous carcinoma.

R. Grunfeld.

Vannini, Angelo. The treatment of conjunctivitis due to Morax-Axenfeld diplobacillus. Rassegna ital. d'ottal. 18 :131-134, March-April, 1949.

In an attempt to determine whether any other medication was equal to or superior to zinc sulfate in the treatment of diplobacillary conjunctivitis Vannini administered sulfonamides, penicillin and streptomycin. While the average time of disappearance of the bacilli was 8 to 10 days with zinc, it was reduced to four days using 30-percent sulfacetamide drops every two hours. Penicillin and streptomycin were wholly ineffective.

Eugene M. Blake.

Venco, Luigi. **Disturbances at the limbus in keratoplasty.** Rassegna ital. d'ottal. 18:65-80, March-April, 1949.

The term "diseases of the limbus," employed by several French ophthalmologists, includes all of the accidents, necroses and opacification which occur at times in well executed corneal transplants. These complications may be divided into precocious necrosis, or that which occurs in the first few days, opacification developing about the third week, and delayed scarring of the transplant. Venco believes that the fundamental factor which determines the changes is trophic and vital and that necrobiotic, anaphylactic and allergic agents are not importnat.

UVEA, SYMPATHETIC DISEASE, AQUEOUS

Alvarez, A. A. **Late syphilitic uveitis healed by penicillin in massive subconjunctival injections.** Ann. d'ocul. 182:521-524, July, 1949.

50,000 units of penicillin with 2-percent novacaine and .1 to 1,000 adrenalin was injected subconjunctivally every six hours during one day. 3,000,000 units were administered intramuscularly during eight days. Improvement promptly followed the treatment in a 42-year-old man with bilateral luetic uveitis which had responded badly to other antiluetic treatment during eight months. Vision improved from .05 to .5.   Chas. A. Bahn.

Blanchi, Guido. **Plastic uveitis in Schoenlein-Henoch disease.** Rassegna ital. d'ottal. 18:114-120, March-April, 1949.

Cutaneous hemorrhages are divided into four groups by Blanchi. They are those associated with 1. avitaminosis (scurvey), 2. hemophilia, 3. essential thrombopenia (Werlhof's disease), and 4. purpora hemorrhagica of Schoenlein-He-

noch. The latter presents a complex picture of an infection which may be acute or with recurrent attacks, and of unknown etiology. The commonest ocular complication is hemorrhage in the retina, under the conjunctiva and in the lids.

Three cases of uveitis are described, the first in a child of one year, resulting in atrophy of the globe. The disease, in the second patient, aged 12 years, ended with a shrunken globe, and in the third, aged 18 years, in a blind eye. All forms of treatment with the usual drugs and antibiotics were unavailing.

Eugene M. Blake.

Custodis, E., and Heineman, K. **Observations of retinal changes in tuberculous meningitis and in miliary tuberculosis.** Klin. Monatsbl. f. Augenh. 114:356-363, 1949.

Sixty-two children with tuberculous meningitis or miliary tuberculosis of the lungs or a combination of the two diseases were observed up to 220 days. Tuberculous infiltrates in the choroid were considerably more frequent in miliary tuberculosis of the lungs, whether it was associated with tuberculous meningitis or not. They were less frequent in patients with tuberculous meningitis who showed no involvement of other organs but even of this latter group 41 percent showed involvement of the choroid, which is a relatively high figure. It is likely that the extended observation made possible by streptomycin brought out changes in the eyegrounds which formerly had not been observed because of the early death of the patient. The authors noted the appearance of fresh tubercles in the choroid in four patients who were under active streptomycin treatment. Most tubercles in the choroid were located near the posterior pole and only very rarely were they found in the equatorial region.

Max Hirshfelder.

François, J. Contribution to the study of the heterochromia of Fuchs and its pupillary sign. (Sympathetic pathogenesis.) Ann. d'ocul. 182:585-596, Aug., 1949.

Earlier conceptions of Fuchs's heterochromia, like those of many other primary constitutional diseases require revision. The disease is not monocular, nor is the lighter eye always the first to show the degenerative changes. A study of the literature and an analysis of nine cases lead the author to believe that Fuchs's heterochromia iridis is essentially a constitutional, degenerative disease which involves especially the anterior uveal tract, and is frequently associated with degenerative changes in the superficial cervical ganglion. The discoloration of the iris is associated with abnormal pigmentation and pigment dispersion. Pigment becomes dispersed and the iris tissue absorbed because of the basic subnormality of the uveal tissue. The associated sympathetic subnormality makes eyes with this disease abnormally sensitive to parasympathetic stimulation, and insensitive to sympathetic stimulation, as is illustrated by the pupillary reactions. The effect of the following drugs, adrenalin, cocaine, acetyl-methyl-chloride, atropine and eserine, on the eyes of the nine patients, was studied. Chas. A. Bahn.

Garden, R. R., and Wear, A. R. Iridoschisis in a case of chronic primary glaucoma. Brit. J. Ophth. 33:509-511, Aug., 1949.

A case of iridoschisis with chronic primary glaucoma is reported. It appears that the basic changes are senile but that the process may be aggravated by proteolytic enzymes in the aqueous and, in this case, the product of glaucomatous metabolism. The change was chiefly in the lower half of the iris and gravity or convection currents may play a part in its development. Orwyn H. Ellis.

Malatesta, C. Rare case of conglomerate tuberculosis of the ciliary body. Boll. d'ocul. 28:223-234, April, 1949.

A 7-months-old boy developed skin eruptions of ulcerative type, swelling of numerous lymphatic nodules, and severe roentgenographic changes in his right lung. The right eyeball was atrophic and showed an almost complete destruction of the cornea and grayish-brown masses protruding from the defect. An eye specialist saw the child 3 months before the admission and found pericorneal injection, and opaque edematous cornea, fibrinous exudation in the shallow anterior chamber, and increased intraocular pressure. The eyeball was finally enucleated; the ciliary body had been replaced by tuberculous granulations. The mother had had an exudative pleuritis before the child was born. There is a discussion of the immunity factor in early life. (3 photomicrographs, references.)

K. W. Ascher.

GLAUCOMA AND OCULAR TENSION

Ascher, K. W. Aqueous veins and their significance for pathogenesis of glaucoma. Arch. Ophth. 42:66-76, July, 1949.

After an excellent and authoritative discussion of aqueous veins, the author concludes that the elimination of intraocular fluid can be studied biomicroscopically. Considered as a unit of clinicopathologic importance, the canal of Schlemm and the aqueous veins show parallel changes in congestion and in inflammation; in primary simple glaucoma their responses are apparently contradictory so far as blood has a tendency to overwhelm the aqueous humor and to stream back against, but not into, the canal, which in eyes with normal pressure often becomes filled with blood during gonioscopic observation. These apparent contradictions can be explained in at least

some cases of glaucoma by the assumption of a narrowing of the canal outlets.

Ralph W. Danielson.

Cristini, Giuseppe. **Cardio-aortic and sinucarotid reflexes in primary glaucoma.** Giorn. ital. oftal. 1:385-403, Sept.-Oct., 1948.

The author discusses the relation between ocular tension and blood pressure and reports his studies of the cardio-aortic and sinucarotid reflexes in primary glaucoma. The stimulation of the vasosensitive areas causes different changes of ocular tension in relation to blood pressure according to whether the patient has high or normal ocular tension at the moment of examination. He analyzes these different reactions that occur in the two stages of glaucoma and calls attention to the consequences that an exaggerated reflex of the vasosensitive area can have on the appearance of an acute attack of glaucoma, and its course.

Vito La Rocca.

D'Ombrain, Arthur. **Traumatic or "concussion" chronic glaucoma.** Brit. J. Ophth. 33:495-500, Aug., 1949.

The observations on a series of cases of monocular chronic congestive glaucoma are presented. It is suggested that there exists a type of chronic glaucoma of traumatic origin. The trauma may produce a chronic process of gradual and progressive blockage of the trabeculum by a sclerotic degeneration or proliferative lesion. The time of onset varies from a few weeks to many years after injury.

. Orwyn H. Ellis.

Galton, E. M. G. **A note on the effect of sleep on glaucoma.** Brit. J. Ophth. 33:511-512, Aug., 1949.

Observations of the effect of sleep on glaucomatous eyes is presented. The rise in tension may be due to immobility of

the lids and eyeballs with consequent lack of massage to the globe.

Orwyn H. Ellis.

Rubino, A. **Trephining and cyclodiathermy associated in the treatment of glaucoma.** Giorn. ital. oftal. 1:450-452, Sept.-Oct., 1948.

The author has associated Elliot's trephining with superficial cyclodiathermy in the treatment of 10 patients with glaucoma for whom the usual methods were not suitable, with favorable results in all. There is a lowering of the tension and a disappearance of inflammation during the year which has elapsed.

Vito La Rocca.

Sanna, M. **The reflexes of Brown-Sequard and of Tholozan in glaucomatous patients.** Boll. d'ocul. 28:193-206, April, 1949.

In order to examine the neurovegetative sympathetic medullary centers, Sanna applied thermic tests to 12 normal and 11 glaucomatous patients. While the right hand was immersed in water, the skin temperature of the left hand was registered at 5-minute intervals. To provoke vasodilatation, water at 42 to 45 degrees C. was used; for vasoconstriction, water at 10 degrees C. Skin temperatures were measured with the thermoelectric device "Thykos." A tendency to or a definite vasoconstrictive tonicity of the circulatory system was found in 8 of 11 glaucomatous patients while only 7 of the 12 now glaucomatous showed this tendency. In 10 of 11 glaucomatous patients a "lassitude of the vasoconstrictive sympathetic medullary centers" was found.

K. W. Ascher.

Stanworth, A. **The cornea in polarised light (preliminary communication).** Brit. J. Ophth. 33:485-490, Aug., 1949.

Corneal strips from cats' eyes were ex-

amined under polarised light. The birefringence of the corneal lamellæ rapidly increases with elongation of the strips. In a physiological range there should be a fairly rapid increase of birefringence with a rise in intraocular pressure. The results suggest that further studies may make the measurement of stress-birefringence available as an optical method for measuring changes in intraocular pressure. Orwyn H. Ellis.

Wolff, Eugene. **The subconjunctival ab externo approach in glaucoma.** Brit. J. Ophth. 33:514-518, Aug., 1949.

The use of a subconjunctival ab externo incision in glaucoma facilitates the performance of filtering operations. The procedure is described in detail. The conjunctival flap is retracted by the assistant with a nontoothed forceps. The operator fixes the eye with a scleral hook and makes the incision into the anterior chamber with a sharp scalpel. The safety and relative ease of performance are stressed. Orwyn H. Ellis.

10
CRYSTALLINE LENS

Davids, B. **Genesis of the complicated cataract.** Arch. f. Ophth. 149:156-175, 1949.

The cataracta complicata as well as the X-ray cataract are interpreted as sequelae of an injury to the lense epithelium which results in a necrobiosis of cells and fibers and the development of generations of pathologic cells. Other types of cataract also show epithelial changes. Quantum processes are considered as genetic factors of these pathologic processes.
Ernst Schmerl.

Gasteiger, H. **Cataract extraction in trephined eyes.** Klin. Monatsbl. f. Augenh. 114:370-385, 1949.

The result of cataract extraction in 44

eyes which had had trephine surgery for glaucoma are reported. It is estimated that cataract follows 10 percent of all trephine surgery, but is not more frequent after trephining than after any other glaucoma operation. Eyes which require multiple glaucoma surgery more frequently develop lens opacities. The author favors intracapsular extraction. His section is usually a Graefe incision without conjunctival flap and avoids the filtering bleb. Cataract extraction did not influence the ocular tension and the visual field unfavorably, and normal intraocular pressure previously established by the trephine operation was usually maintained. (1 figure, references.)
Max Hirschfelder.

Harrington, D. O. **Mechanics of intracapsular cataract extraction.** Arch. Ophth. 42:23-41, July, 1949.

In order to acquire the greatest proficiency in intracapsular cataract extraction the surgeon should have an understanding of the physical principles underlying the dislocation and delivery of the lens. It can be demonstrated by slit lamp microscopy and by gonioscopic observation during actual intracapsular cataract extraction in the eye of a living animal and a human cadaver that the rupture of the zonular lamella of the lens is accomplished primarily by the production by external pressure of a wedge of vitreous, which is made to insert itself between the equator of the lens and the ciliary processes. This deformity of the vitreous can be produced by choosing the method and the point of application of the external pressure at whatever site is desired so that one may tumble or slide the lens from its position in the hyaloid fossa. The normal vitreous is a tissue and cannot be considered as a fluid in which pressure at one point is transmitted equally to all other parts. Capsular trac-

tion facilitates dislocation of the lens by stretching the zonule, but does not normally produce its rupture.

Ralph W. Danielson.

Kuhn, H. A., and Kuhn, H. S. **Monocular cataracts: industrial implications.** Tr. Am. Acad. Ophth. pp. 682-686, July-Aug., 1949.

Should a monocular cataract in an industrial patient be extracted if vision in the other eye is normal? Eighty-two such lens extractions are analyzed to show that the risks, cost and discomforts of operation are justified in some cases. Among the potential advantages are better vision for positions requiring binocular vision, a favorable time for cataract extraction and relative infrequency of postoperative discomfort. Chas. A. Bahn.

11
RETINA AND VITREOUS

Campos, R. **Vitreous-body detachment and its relation to retinal detachment.** Boll. d'ocul. 28:12-154, March, 19949.

Detachment of the vitreous body was first described anatomically by H. Müller in 1856 and ophthalmoscopically by L. Weiss 41 years later; in 1922 the first biomicroscopic description was made by Pillat. Campos summarizes previous classifications distinguishing prebasal and retrobasal detachments; the latter may begin in the upper or in the posterior part of the vitreous body. According to the distance between retina and hyaloid membrane the posterior detachment may be incomplete or complete. Lateral detachments are questionable. Etiologic factors are inflammation, senile changes and degeneration of the colloids constituting the vitreous-body framework. Subjective symptoms are scarce: phosphenes of short or longer duration occur. The first to assume a possible connection between traction of the vitreous body and retinal de-

tachment was Iwanoff (1869). Leber and Nordenson described preretinal fibrous threads formed by proliferating cells; Gonin (1918) concluded, from the shape of most of the retinal holes, that vitreous traction on the retina was responsible for retinal detachment. This theory found numerous defenders but Vogt doubted the importance of traction and stressed peripheral and macular cystic degeneration of the retina as the main etiologic factor in detachment. Campos studied 60 eyes with retinal detachment, using Lindner's angular corneal microscope with arc light and the −55.0-diopter lens of Hruby. In 66 to 93 percent of eyes with retinal detachment, vitreous detachment was present. The highest precentage occurred in the aged and those with high myopia. The fellow eyes showed vitreous detachments in more than 60 percent of the eyes. (51 references.) K. W. Ascher.

Delaney, A. J., and Rhoades, A. L. **Angioid streaks of the retina: case report.** U.S. Naval Med. Bull. 49:572-574, May-June, 1949.

Angioid streaks of the retina occurred in a patient who had pseudoxanthoma elasticum. Donald T. Hughson.

Gandolfi, C. **Pathogenesis of retinitis circinata.** Giorn. ital. oftal. 1:425-431, Sept.-Oct., 1948.

A case of retinitis circinata with senile macular degeneration and numerous scattered spots at the periphery is reported. The author believes that retinitis circinata, like macular degeneration and scattered retinitis, is a manifestation of angiopathy of the retina. Vito La Rocca.

Herson, R. N., and Sampson, R. **Ocular manifestations of polyarteritis nodosa.** Quart. J. Med. 18:123-132, April, 1949.

The authors report the ophthalmoscopic findings in four patients with polyarteritis

nodosa who later came to autopsy. The ophthalmoscopic signs began with blurring of the edges of the disc and with one or two small hemorrhages adjacent to it. Soon wide areas of retinal edema appeared and detachments of the retina of various sizes occurred with spontaneous recovery sometimes in less than three weeks. In three cases nodules of choroiditis were found which rapidly progressed to the formation of pigmented scars. In one case the retinal arteries were directly affected by the polyarteritic process. Arteritis, obstruction of lumen, aneurysmal dilatation, and scar formation could be observed in succession. The ocular findings have a grave prognostic significance. The average duration of life in all four cases was about six weeks after the discovery of the first eye signs.   R. Grunfeld.

Jahnke, W. Treatment of retinitis diabetica with insulin. Arch. f. Ophth. 149: 240-247, 1949.

Vasodilatation and increased capillary permeability are considered the dangers in the treatment with insulin. The author recommends that a blood sugar level of from 130 to 160 mg. percent be maintained.   Ernst Schmerl.

McLean, M., and Solanes, M. Anticoagulant therapy in retinal vascular occlusion. Tr. Am. Acad. Ophth. pp. 644-657, July-Aug., 1949.

The pharmacology of heparin and dicumarol are briefly discussed. The former is administered only intravenously and preferably in 50 to 100-mg. doses at 4 to 6-hour intervals. The latter, which is slower in action, is preferably administered orally as capsules. The initial dose is 200 to 300 mg. and the maintenance dose is 50 to 200 mg. If complications ensue the drugs are discontinued and whole blood or vitamin K are administered intravenously. Forty-one patients treated with anticoagulants are reported. In venous occlusions a subendothelial and endothelial proliferation apparently occurs with the formation of a canalized thrombus. Anticoagulants apparently act by decreasing or slowing the accelerated rate of blood clotting and thus inhibit the formation of additional clots. Anticoagulant therapy should be started soon after the condition occurs and should be continued until the prognosis is determined. Although visual improvement occurred in a number of the cases treated with anticoagulant therapy, its specific indications have not yet been accurately determined.   Chas. A. Bahn.

Rosengren, Bengt. Pathogenesis of fundus changes in arterial hypertension. Klin. Monatsbl. f. Augenh. 114:328-333, 1949.

The vascular changes in the retina in benign hypertension are similar to those found in other organs, mainly those in the region of the splanchnic nerve. In malignant hypertension the process is exudative with edema and hemorrhages superimposed on very constricted arteries. Proliferation of the intima, hyaline degeneration of the media, fibrinoid degeneration of the adventitia are found. The author doubts that the retinal changes are a result of mere ischemia and points to cases of complete ischemia due to arterial occlusion which in no way resembled the picture of malignant hypertension. Renal insufficiency does not in itself explain the fundus changes. The possibility of a toxic substance as well as a purely mechanically damaging effect in hypertension must be considered.
          Max Hirschfelder.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.

601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month but, to receive adequate publicity, notices of postgraduate courses, meetings, and so forth should be received by the editor at least three months before the date of occurrence.

DEATHS

Dr. Lloyd Glenn Dack, St. Paul, Minnesota, died July 9, 1949, aged 59 years.

Dr. Clyde Elliott McDannald, New York, New York, died August 13, 1949, aged 73 years.

Dr. William Denton Rowland, Boston, Massachusetts, died July 1, 1949, aged 69 years.

ANNOUNCEMENTS

SCHOENBERG MEMORIAL LECTURE

The Mark J. Schoenberg Memorial Lecture will be held at the New York Academy of Medicine at 8:30 p.m., Monday, December 5th, under the joint sponsorship of the New York Society for Clinical Ophthalmology and the National Society for the Prevention of Blindness. Dr. Jonas S. Friedenwald, Baltimore, Maryland, will discuss "Some problems in the diagnosis and treatment of glaucoma."

This lectureship was established as a memorial to Dr. Schoenberg's interest and original work in the control of glaucoma.

On the committee in charge of arrangements for the meeting are Dr. Willis S. Knighton, chairman; Dr. Isadore Givner, Dr. James W. Smith, and Dr. Franklin M. Foote.

TEMPLE FACULTY PROMOTIONS

The following promotions have been made on the faculty of the Temple University School of Medicine: Dr. Robison D. Harley from associate to assistant professor of ophthalmology; Dr. William Hart from associate to assistant professor of ophthalmology; and Dr. Louis Hinman from instructor to associate of ophthalmology.

WILDER MEMORIAL LECTURE

The William Hamlin Wilder Memorial Lecture, "Medical ophthalmology: A Kodachrome demonstration of fundus photographs of diabetes, hypertension, nephritis, optic neuritis and choked disc," was delivered by Dr. Arthur·J. Bedell, Albany, New York, at a joint meeting of the Institute of Medicine of Chicago and the Chicago Ophthalmological Society on October 14th in Chicago.

SOCIETIES

READING SOCIETY

The 96th meeting of the Reading Eye, Ear, Nose, and Throat Society and the sixth joint meeting with the Berks County Medical Society was held on September 13th. It was a symposium on diabetes. Dr. Milton P. Adel, New York City, discussed "What can the internist tell us?" and Dr. Irving H. Leopold, Philadelphia, "How does the ophthalmologist help?"

Officers of the Reading Society for the year 1949 to 1950 are: President, Dr. William J. Hertz, Allentown; 1st vice-president, Dr. John M. Wotring, Reading; 2nd vice-president and president-elect, Dr. Roy Deck, Lancaster; treasurer, Dr. Philip R. Wiest, Reading; secretary, Dr. Paul C. Craig, Reading; program chairman, Dr. C. Fremont Hall, Phoenixville.

PERSONALS

MADE HONORARY MEMBER

On Friday, October 21st, at the annual convocation of the American College of Surgeons, Sir Stewart Duke-Elder was installed as an honorary member of the organization in a colorful ceremony.

AWARDED LESLIE DANA MEDAL

Dr. Conrad Berens, New York, was awarded the Leslie Dana Medal for the Prevention of Blindness in recognition of his outstanding contributions to ophthalmology at a dinner in his honor at the Chase Hotel, Saint Louis, Missouri, on October 15th. The medal is presented by the Saint Louis Society for the Blind in coöperation with the National Society for the Prevention of Blindness and the Association for Research in Ophthalmology.

GIVES LECTURE IN CUBA

Capt. Arthur Alexander Knapp (MC) U.S.N.R., has recently returned from Havana, Cuba, where he conducted a course in "Plastic surgery of the eye," at the university and presented a paper on "Highlights of eye surgery," before the Cuban Ophthalmological Society.

LECTURES IN TENNESSEE

Dr. Arthur J. Bedell, Albany, New York, delivered a lecture entitled, "The ophthalmoscopic signs of constitutional disease," before the Nashville Academy of Medicine and Davidson County Medical Society on October 5th in Nashville, Tennessee.

To reduce the   blinding pressure

'FURMETHIDE' (furtrethonium iodide, S.K.F.) — cholinergic drug developed through S.K.F. Laboratories research — has been found exceptionally effective in reducing intra-ocular pressure in a wide range of glaucomatous conditions, both primary and secondary.

Salient Facts:

1.. 'Furmethide' Ophthalmic Solution is non-irritating even on prolonged use and rarely, if ever, produces systemic reactions.

2.. The development of tolerance or sensitivity to 'Furmethide' has not been encountered.

3.. Because of its unique resistance to cholinesterase, 'Furmethide' does not require the use of a cholinesterase inhibitor.

4.. Its successful use has been particularly noteworthy in many cases in which other miotics failed.

An important contribution to GLAUCOMA therapy

RETROLENTAL FIBROPLASIA IN PREMATURE INFANTS*

II. STUDIES ON THE PROPHYLAXIS OF THE DISEASE: THE USE OF ALPHA TOCOPHERYL ACETATE

WILLIAM COUNCILMAN OWENS, M.D., AND ELLA UHLER OWENS, M.D.

Baltimore, Maryland

A new concept of retrolental fibroplasia was introduced by our previously reported observations on the early stages and development of the disease.[1] These observations demonstrated that retrolental fibroplasia starts in the retina with an acute onset in postnatal life and runs an active course, which gradually subsides. The final picture depends upon the severity of the acute phase and the extent of contracture of the fibrous tissue formed during the active stage of the disease.

Retrolental fibroplasia was first brought to attention by Terry,[2] who described the appearance of the fully developed disease and pointed out the relationship of the disease to prematurity. Reese and Payne,[3] Krause,[4] and Klien[5] made further reports on cases they had observed in the late stages of the disease.

In the earlier literature there was considerable difference of opinion as to the nature and origin of the membrane behind the lens. Various hypotheses had been proposed relating the disease to the persistence and overgrowth of the hyaloid artery or primary vitreous, or to a generalized maldevelopment of both the cerebral and ocular neuroectoderm occurring during the early stages of fetal life. In addition the question of whether or not the disease was present at birth remained unsettled.

The main reason for these differences in opinion arose from the fact that the earlier reports had been limited almost entirely to clinical and pathologic examinations made when the disease was well advanced. None of the earlier observers had seen where the disease started, when it first began, or how it progressed. It therefore seemed logical that the first step in the investigation of the pathogenesis should be the observation of the onset and course of the disease. To do this, it was necessary to make observations on prematurely born children shortly after birth and to continue the observations periodically until the disease had reached the end stages described by the previous investigators.

The observations made on this plan showed that retrolental fibroplasia was not present at birth. No differences were found on early examinations between the eyes that subsequently developed retrolental fibroplasia and those that did not. The earliest detectable change, occurring about 3 to 5 weeks after birth, was a dilatation of the retinal veins and an increased tortuosity of the retinal arteries. Localized or generalized swelling of the retina soon followed, and the retina developed a grayish-green color. Often the retina became so swollen that the course of the retinal vessels could not be traced in the areas of greatest retinal edema. The vitreous became cloudy and proliferating fibrous bands extended forward from the elevated retina into the vitreous. The retrolental membrane was formed by the

fusion of the vitreous bands and the peripheral folds of swollen elevated retina. These findings have been confirmed by Falls,[6] Unsworth,[7] and Gilger.[8]

The active phase of the disease usually stops between the 4th and 5th month of the infant's life, and the changes that occur after this time are due to contracture of previously formed fibrous tissue. If the membrane behind the lens is complete, all vision is lost. Occasionally the disease is not so extensive and, when it subsides, only a partial membrane or a band resembling a retinal fold is formed. These eyes are often myopic and may show disseminated areas of irregular pigmentation. Some vision is retained and children with this less severe involvement see well enough to walk alone and play with toys. In premature infants both eyes are affected by the disease, but often to various degrees. The membrane may be complete in one eye and only partial in the other.

The main problem in retrolental fibroplasia is the prophylaxis of the disease rather than treatment in the late stages when irreversible damage has been done to the retina. No treatment has yet been found which is of value when the disease is well established. Operations to remove the membrane have been unsuccessful, for a portion of the retina itself is excised in the attempt to clear the retrolental space. The description of the onset and course of retrolental fibroplasia has redirected most of the thinking about the disease. Formerly, emphasis was placed on factors which might have been effective in the prenatal life of the infants[9] or to an abnormal persistence of various fetal structures. It is now evident that the most fruitful investigation is to be found in a study of factors which are active in postnatal life.

ETIOLOGIC CONSIDERATIONS

In our first report the idea was proposed that the disease might be related to a metabolic disturbance produced by some of the newer methods used in the care of premature infants to compensate for their physiologic immaturity. The close correlation between the incidence of retrolental fibroplasia and the birth weight of the infant adds support to the theory that a metabolic abnormality may be the cause of the disease.

One of the main physiologic differences between the premature and the full-term infant is the defective fat metabolism of the premature infant.[10] Because of this defect, premature infants have been given diets low in fat and high in protein as they apparently can utilize protein efficiently.[11]

Shortly after the high protein diets were introduced it was found that a disturbance was created in the metabolism of the aromatic amino acids. Phenylalanine and tyrosine were found to be incompletely oxidized and the intermediary products p-hydroxyphenyl pyruvic and p-hydroxyphenyl lactic acid appeared in the urine. This abnormal metabolism of aromatic amino acids could be prevented by increasing the amount of vitamin C in the diet.[12] It seemed possible that some similar metabolic disturbance might be the basis for the occurrence of retrolental fibroplasia.

The low fat diet recommended for premature infants contains very little of the fat-soluble vitamins. In view of this fact and the poor absorption of fats by the premature infant, a minimal supply of fat-soluble vitamins would be available to the premature infant were they not supplemented. It seems probable that the premature infant might have a marginal prenatal storage of a necessary fat-soluble substance. As this substance is depleted or the need for it increased in postnatal life, the infant might be unable to replenish it from the diet. This hypothesis can be correlated with the clinical observation that the earliest detectable changes of retrolental fibroplasia are noted about one month after birth. Of the fat-soluble vitamins, A, D, K, and E, the vitamins A and D have been provided routinely in large doses in the vitamin supplements currently used. Vitamin K is usually given shortly after birth. Vitamin E alone of the fat-soluble vitamins has not routinely been in-

cluded in the vitamin supplements of premature infants. It is known that regardless of how high the maternal intake of vitamin E may be, the newborn rat begins life with a negligible supply of this vitamin.[13]

In addition to the low vitamin E available in the reduced fat diets, and the poor absorption of fat-soluble substances by the premature infant, the amount of vitamin E available might be further reduced by two factors in the current care of premature infants. The first factor is the use of large amounts of vitamin A given to supplement the diet. The vitamin-A supplements are given usually either in the form of natural fish-liver oils which contain large quantities of unsaturated fats, or as vitamin A in water-miscible preparations. It has been shown that the requirement of vitamin E in experimental animals is increased when vitamin A[14] or when unsaturated fats[15] are administered. This is thought to be due to the role of vitamin E as an antioxidant in protecting the unsaturated carbon bonds in these compounds.[16] Therefore the supplements of large amounts of vitamin A, or of fish-liver oils containing unsaturated fats, might serve to increase the needs for vitamin E in the diet of the premature infant. The use of iron to overcome the anemia which premature infants develop in postnatal life might serve to decrease even further any small amount of vitamin E available to the premature infant. It is well known that ferric salts destroy vitamin E. One of the methods of producing a vitamin-E deficient diet for experimental animals is to treat the ingredients of a full diet with ferric chloride to destroy the vitamin E present.[17]

Kinsey and Zacharias found a positive correlation between the rise in incidence of retrolental fibroplasia and the increased use of water-miscible preparations of vitamins and of iron.[18] The relationship of large supplements of vitamin A and iron to the occurrence of retrolental fibroplasia is still under study. In the premature nursery of The Johns Hopkins Hospital retrolental fibroplasia developed in two infants who had not received vitamin A or iron. Two other children have been seen here with retrolental fibroplasia in the late stages of the disease who had also never received either vitamin A or iron supplements. Kinsey and Zacharias have reported similar cases, and it is likely, as they point out, that the administration of large amounts of vitamin A and iron are not primary factors in the etiology of the disease.

From these considerations, it is apparent that numerous factors in their dietary regime would allow premature infants to have only marginal amounts of vitamin E available. Among these factors are the low fat diet, the poor absorption of fats by the premature infants, the lack of vitamin-E supplements, and the use of such substances as vitamin A, unsaturated fats, and iron, all of which might increase the need for vitamin E.

In addition, the relative importance of fat metabolism in the immediate neonatal period, plus the predominant absorption of unsaturated fatty acids by the premature infant might further increase the vitamin-E requirements in this critical period.[10] Soon after birth, newborn infants have a sudden increase in the metabolism of lipoid substances. The fetus probably uses little fat for its heat production but stores considerable for later emergencies. After the newborn infant has fairly well depleted its glycogen stores, it begins to depend largely upon reserves of fat for energy. There is a greatly increased transport of fat substances in the blood so that the concentration of most types of blood fat are roughly doubled between birth and the second week of life.[19] Recent studies on the biochemical function of vitamin E indicate that many of its physiologic effects are related to its antioxidant properties, especially in relation to fat metabolism. Vitamin E functioning as an antioxidant plays an important role in protecting or stabilizing unsaturated fats during their mobilization, metabolism, and storage within tissue cells.[20]

The immature organism is particularly

susceptible to vitamin-E deficiency. Nursing rats born of vitamin-E depleted mothers develop acute muscular dystrophy 17 to 19 days after birth.[21] Young chickens, placed on a vitamin-E deficient diet at the time of hatching, suddenly develop nutritional encephalomalacia at 3 to 4 weeks of age.[22] This disease is characterized by areas of edema, hemorrhage, necrosis, and glial proliferation in the central nervous system. In each of these diseases, there is an age limit to the susceptibility of the animals to the nutritional derangement. As they grow older the incidence of the disease steadily decreases.[23] This susceptibility of immature animals to vitamin-E deficiency might be paralleled by the susceptibility of premature infants to retrolental fibroplasia.

A further function of vitamin E is to control excessive tissue oxidation. The lowering of the oxygen consumption of brain homogenates of vitamin-E deficient animals by alpha tocopheryl phosphate appears to be due to the prevention of the reduction of cytochrome-C wherever the cytochrome system comes into play; whether in carbohydrate, fat, or protein metabolism.[24] Since the retina has a higher rate of respiration than that of almost any other tissue,[25] and since the premature infant is characteristically in a marginal status of anoxia[10] vitamin-E supplements might be expected to play a role in the prevention of retrolental fibroplasia through this function.

These considerations immediately raised the question whether supplements of vitamin E might prove to be a factor in the prevention of retrolental fibroplasia. In an effort to study the problem of retrolental fibroplasia from this standpoint, a series of laboratory and clinical investigations have been undertaken. These investigations are still in progress, and this report covers only the observations on the clinical aspects. The results of the laboratory studies will be reported in another paper.

CLINICAL STUDY

The clinical study on the use of dl alpha

tocopheryl acetate was begun in June, 1948. At that time the only available preparation suitable for premature infants was a mixture of natural tocopherols of low potency. Vitamin-E activity is possessed by three higher alcohols known as alpha, beta, and gamma tocopherol. Alpha tocopherol has the greatest biologic activity of these three forms. Tocopherols are widely distributed in vegetable oils and in lesser concentration in animal fats. Their esters are much more stable than the free forms.[26] Synthetic dl alpha tocopheryl acetate has been accepted as the international standard of vitamin E.[27] In July, 1948, a special preparation of synthetic dl alpha tocopheryl acetate in a water-miscible menstrum was obtained.*

For a period of 10 months, alternate infants admitted to the premature nursery of The Johns Hopkins Hospital with birth weights of three pounds (1,360 gm.) or less were given supplements of this preparation. The dose used was 150 mg. daily, given orally in 50 mg. doses every eight hours between feedings. This was started as soon after birth as the infant was able to take feedings by gavage or by mouth. Most of the infants in each group received 9,000 units of vitamin A and 900 units of vitamin D daily in a water-miscible preparation. About one third of the infants in each group received 4 cc. of a 10-percent solution of ferric ammonium citrate daily. This iron supplement was begun when the infants were six weeks of age.

During this 10-month period, 11 infants received vitamin-E supplements and none developed retrolental fibroplasia. Fifteen infants in the control group did not receive vitamin E, and five of these developed retrolental fibroplasia.

These results were so encouraging that in May, 1949, the plan was changed and vitamin-E supplements were given to all premature infants weighing three pounds (1,360 gm.) or less at birth. The routine ad-

ministration of vitamin A and iron was discontinued. Each infant was given 500 units of vitamin D daily in a water-miscible preparation. Since this time 12 infants have received alpha tocopherol supplements.

One of them has developed retrolental fibroplasia, showing massive retinal folds extending from the disc to the periphery of the fundus in each eye. The neonatal course of this infant was unusual. The birth weight of the infant was 1,110 gm. This fell to 880 gm. by the second week of life. The infant was apneic and cyanotic, and not expected to survive. Because of its poor condition, the only nourishment it received for 11 days after birth was parenteral glucose and amigen. From the 11th to the 15th day, feedings by gavage could be given, but only glucose solution was tolerated. On the 15th day, milk feedings could be substituted for the glucose solution. It was necessary to continue feedings by gavage until the infant was six weeks of age. The alpha tocopherol could not be started until the 11th day when feedings by gavage were begun.

Before the time alpha tocopheryl acetate was used, a total of 63 infants weighing less than three pounds at birth were followed routinely. Of these, 12 developed retrolental fibroplasia.

In summary the experience with the entire group of infants followed routinely from birth can be divided into three periods: (1) The period before the use of alpha tocopheryl acetate supplements, (2) the period during which alternate infants were given alpha tocopheryl acetate supplements, and (3) the period during which all infants were given the supplements. All of these infants had a birth weight of three pounds (1,360 gm.) or less. A total of 101 infants was observed. Seventy-eight of these did not receive alpha tocopheryl acetate supplements. Seventeen of these (21.8 percent) developed retrolental fibroplasia. In contrast, 23 infants received alpha tocopheryl acetate supplements. Only one of these (4.4 percent) developed retrolental fibroplasia (table 1).

As mentioned before, during the period when alternate infants with birth weights of 1,360 gm. (three pounds) or less were given tocopherol supplements, five infants in the unsupplemented group developed the early stages of retrolental fibroplasia. In addition four infants in the group weighing over 1,360 grams who did not receive vitamin E prophylactically showed the early stages of the disease. The preparation of dl alpha tocopheryl acetate was used in these nine babies to determine whether vitamin-E supplements would alter the course of the disease in its early stages. Vitamin A and iron preparations were withheld from these infants when the vitamin-E supplements were begun. Under this regime, progress of the lesions was arrested in five cases. In the other four cases, the course of the disease was unaffected by the supplement. Spontaneous regression of the disease after the stage of diffuse retinal exudation is unusual.

In our experience thus far, vitamin-E supplements are of no value if not started at least before the baby is six weeks of age, since by that time irreversible retinal changes have occurred. The supplement must be started early before the retina has become detached and visible as a partial or complete membrane behind the lens. It is of no value when the disease is recognized grossly by the parents or doctor by external examination.

No serum levels of vitamin E in prema-

TABLE 1

EFFECT OF VITAMIN E SUPPLEMENTS ON THE INCIDENCE OF RETROLENTAL FIBROPLASIA IN PREMATURE INFANTS WITH BIRTH WEIGHTS OF THREE POUNDS (1,360 GM.) OR LESS

Diet	Number of Infants	Number with Retrolental Fibroplasia	Percent Retrolental Fibroplasia
Supplemented with Vitamin E	23	1	4.4
Not Supplemented with Vitamin E	78	17	21.8

ture infants have been reported in the literature. The normal level in adults has been found to vary from 1.0 to 1.2 mg. percent.[30] Only a few determinations have been reported on full-term newborn infants. These levels were significantly lower than the maternal levels, and varied from 0.2 to 0.5 mg. percent.[31, 32]

Determinations of the vitamin-E levels of the serum have been made in the course of this study. At first the determinations were made by a method[28] which required 5 cc. of blood—an amount which was not feasible to obtain frequently from small premature infants. It became evident that a micromethod for determining vitamin E was essential. Dr. V. E. Kinsey solved this problem for us by adapting a method devised by M. L. Quaife which requires only 0.2 cc. of serum.[29] The vitamin-E determinations on the sera are being made at present under Dr. Kinsey's direction at the Harvard Medical School. Forty-six determinations of the vitamin-E level were made on sera of premature infants who were receiving no vitamin-E supplements. The average level in these determinations was 0.25 mg. percent. When dl alpha tocopheryl acetate was given, the serum level rose with increasing supplements. The average vitamin-E level was 4.12 mg. percent in 103 determinations made on sera of infants receiving 150 mg. dl alpha tocopheryl acetate daily. Most of these infants had birth weights of three pounds or less, and the sera were obtained from 2 to 8 weeks after birth.

It is important to follow the serum level of tocopherol for, in a few of our cases, the serum tocopherol level did not rise even though the infants were receiving large oral supplements of dl alpha tocopheryl acetate. The problem of parenteral administration of alpha tocopherol to premature infants who show evidence of inadequate absorption by the oral route is now being investigated.

COMMENT

In evaluating our experience with tocopherol supplements, there are several observations for which an explanation is not readily available. There appears to be no constant correlation between the serum tocopherol level and the occurrence of retrolental fibroplasia. Some of the infants in the unsupplemented group who developed retrolental fibroplasia did not have lower tocopherol levels than some infants in the same group who did not develop the disease. In addition the one infant in the supplemented group who developed retrolental fibroplasia showed progression of the disease even though the serum tocopherol level was adequate from the time the first retinal changes were observed at six weeks of life. As stated before the exact mechanism whereby vitamin E functions in the body is not known. It seems apparent, however, that at the high serum tocopherol levels we have obtained, the tocopherol is not exerting a true vitamin function but rather a pharmacologic action as suggested by Harris.[33]

The material presented in this paper is the report of studies still in progress. It must be remembered that, as yet, no claims for the role of vitamin E in human nutrition have been substantiated, although its role in animal nutrition has been well established. So far the results in the prophylaxis of retrolental fibroplasia have been encouraging, and it is planned to continue these studies until sufficient data have been accumulated to evaluate critically the role of vitamin E in relation to this disease. It seems certain that the solution to the etiology of retrolental fibroplasia will be found from such a metabolic study.

CONCLUSIONS

1. A total of 101 premature infants with birth weights of 1,360 gm. (three pounds) or less have been observed at routine intervals since birth. Twenty-three of these infants received supplements of dl alpha tocopheryl acetate. One of these (4.4 percent) developed retrolental fibroplasia. Seventy-eight infants did not receive supplements of dl alpha tocopheryl acetate. Seventeen of these (21.8 percent) developed retrolental fibroplasia.

2. The average serum tocopherol level in the unsupplemented group of premature infants was 0.25 mg. percent. On a dosage of 50 mg. of dl alpha tocopheryl acetate every eight hours, the average serum tocopherol level rose to 4.12 mg. percent.

THE PHYSIOLOGY OF THE INTRAOCULAR FLUIDS
AND ITS CLINICAL SIGNIFICANCE*

STEWART DUKE-ELDER,† M.D.
London, England

I find it impossible to proceed with this lecture without a preface recording my great appreciation of the fact that this academy has made me its guest of honor. I know that on an occasion such as this it is the usual and graceful habit of the lecturer to express such thanks; but in this case I would wish you to believe that my thanks are more than usually sincere and from the heart. Before the war on more than one occasion I was a guest in this great country and drank deep of American hospitality. During the war one of the good things—and there are some good things even in war—was the close association which I and my British colleagues had with Americans, particularly American ophthalmologists. After the war one of the sorrows of peace was the departure of our American friends from England; but I, for my part, having grown used to your company, have made up for my loss by recurrent invasions of your country. In 1946, I was made the guest of honor of the select company of the American Ophthalmological Society and also of the Association for Research; in 1947, I was again the guest of honor of the wider company of the ophthalmologic section of the American Medical Association; and today I am overwhelmed by a similar courtesy from what must certainly be the largest convention of ophthalmologists in this world. I have to thank you, Mr. President, and your council —and you all—for thus filling my cup to overflowing; and I hope you will believe me when I assure you that to come and be with you is to me not to come amongst strangers to a foreign land, but to meet again very

old and very dear friends—to go, as it were, from one room to another in my own home through a door which is never locked.

Some of you may remember that about a quarter of a century ago I summarized my early work on the problem of the mechanism of the formation of the intraocular fluids in a monograph wherein I stated, unequivocally and with all the assurance of youth, that the aqueous humor was a dialysate of the capillary blood. Fortunately I had the wisdom, even in those days, to end the monograph thus: "This is to be accepted in the light of a working hypothesis which may, or may not, aid after the manner of a temporary scaffolding in the erection of a building of whose very design we are ignorant, and as such it is to be treated. For the whole progress of knowledge is strewn with the wrecks of such systems." However much or little the formulation of this hypothesis stimulated work on this problem, the fact remains that today such a theory can no longer stand alone: it is to explore what must take its place and what practical lessons must follow that is the purpose of this address.

This necessity to discard a hypothesis, of course, is not at all uncommon in the advance of any science and is essentially a sign of progress. The methods of investigation available 25 years ago were crude in comparison with those of today: they produced results with a large margin of error which could be synthesized into broad and apparently satisfying generalizations. But today the introduction and evolution of improved and novel techniques have changed all this. The accuracy of chemical analyses, particularly of minute quantities of fluids, has improved enormously; but what is of much greater importance, to the chemistry of molecules there has been added the physics

of radioactive tracer elements whereby we can follow metabolic processes throughout all their intricacies without, so far as we know, upsetting the normal metabolism. By these electronic techniques it is relatively easy to determine the rate of penetration of a given element from the blood stream into the uvea, the aqueous humor, the vitreous, the lens, or the cornea in quantities so minute as to be quite outside the range of chemical analysis. With this technique we have gained immeasurably in refinement of accuracy, ease in manipulation, and—a very important point—in lack of disturbance of the natural conditions.

It is not surprising that with these new weapons at our disposal, with all their refinement of accuracy, we are getting results differing from the old and we have been confronted with many new awkward facts which will not fit in with a picture so simple as that of a dialysate. It follows that the conception of a dialysate must be abandoned and something else must take its place. It frequently occurs, however, that in the evolution of science from a relatively simple to a more complex stage, the transference is a period of considerable confusion and complexity. To a large extent we are at present in the confusion of this interim period, and so, if I choose this opportunity to put forward a new theory, I would hasten to deprive it of any proved or pragmatic significance. If it merely serves as another temporary scaffolding whereon to build and eventually has to be discarded on the discovery of further new facts, it may have served its purpose of ordering our present knowledge and stimulating new avenues for research.

I like to think it is often valuable and frequently stimulating not to make our science too rigid and pontifical, but to anticipate that which is wholly verifiable. Those who refuse to go beyond fact rarely get as far as fact; they will miss much of the fun of life. Goethe may have been right when he said that hypotheses are cradle songs which lull to sleep; but if one sleeps one may dream dreams, and perhaps awake to write a sonnet. And if for a few days I have escaped from the factual fetters of nationalized medicine in Britain into a community where medicine is still—if perhaps only temporarily—free, I hope to make the most of my liberty and take you along with me on a journey in the hope that, even if we do not reach the end with certainty, we may find some illumination by the way. In any event the journeying is always more pleasant than reaching the goal.

Here then are some facts.

I do not think there is any doubt but that the essential blood-aqueous barrier is the capillary walls, as in fact they are the blood-tissue barrier elsewhere in the body. It is true that in the ciliary region the further barrier of the ciliary epithelium is interposed, which, as we shall see presently, exerts a considerable influence on the composition of the intraocular fluid; but on the anterior surface of the iris there is no other barrier, for there the capillaries are naked to the aqueous, and posteriorly the tenuous internal limiting membrane of the retina can have little physiologic significance. A multitude of experiments on the transfer of materials both naturally occurring and artificially injected, both in the normal state and in conditions of increased capillary permeability, as well as clinical facts such as the possibility of the maintenance of a relatively normal physiology when the eye is divided into compartments by a seclusion of the pupil, leave little doubt that an exchange between blood and intraocular fluid throughout the vascularized tissues of the eye constitutes the background of the metabolic interchange.

With this premise I want to examine for a moment the transfer of material across the walls of the ocular capillaries. Table 1 indicates the rate of transfer both into the aqueous humor and into the vitreous body of certain substances. These substances are chosen from many on which we have ex-

perimented as being typical examples of classes, and for comparative purposes their respective rates are expressed in terms of a constant which has a relative but no absolute significance.

TABLE 1

RATE OF TRANSFER: BLOOD→EYE

Substance (and molecular weight)		Aqueous K_{Aq}	Vitreous K_V
Water	(18)	600	—
Lipoid Soluble Substances:			
Ethyl alcohol	(46)	250	150
Sulfapyridine	(249)	100	30
Thiourea	(76)	70	—
Sugars:			
Glucose	(180)	34	11
Sucrose	(342)	5	0.29
Inulin	(5000)	nil	nil
Ions:			
Sodium	(23)	40	7.5
Chloride	(35)	40	6
Thiocyanate	(58)	46	7.5
Nitrogenous Substances:			
Urea	(60)	14	1
Amino acids	(75)	14	0.3
Penicillin	(334)	1.3	nil
Proteins: (70,000–140,000)		nil	nil

In this table several things are of significance. In the first place, water gets through from the blood into the anterior chamber with the greatest of ease; proteins, with their gigantic molecules, hardly at all. In the second place, all the other diffusible substances get through comparatively slowly into the anterior segment, and with much greater difficulty and much more selectively into the posterior segment. In general terms the rate of entry is governed not by molecular size, as in physical diffusion, but by the chemical nature. Thus lipoid-soluble substances get through most readily, nitrogenous substances with the greatest difficulty. That some physical basis exists is suggested by the fact that within each group of substances the retardation varies to some extent with the molecular size—ethyl alcohol passes more quickly than the sulfa drugs, the monosaccharides more quickly than the di-

saccharides, urea than penicillin, and so on. But by and large, a physical differentiation does not apply. Here we see an unusual delay in the passage of all molecules; an equality of the rate of passage of molecules of different size (when sodium and glucose enter at much the same rate); a block to the passage of nitrogen-containing molecules (whereby amino acids enter more slowly than glucose, the molecule of which is twice the size—or penicillin lags behind sucrose); and a facilitation of lipoid-soluble molecules (whereby the rate of penetration of sulfapyridine is over 20 times that of sucrose although the molecule is only slightly smaller, or the translation of urea to the larger molecule of thiourea increases its ease of passage five times). Clearly the passage is not on a physical basis but to a large extent is determined chemically. It is important also that synthetic substances, such as trimethyl glucose, which do not participate in metabolic activity in vivo, enter at the same rate as corresponding natural substances so that the process of transfer in their regard, at any rate, does not seem to be a secretion.

In the posterior segment of the eye this tendency is more accentuated. The chemical differentiation is greater and, what is more interesting, a regional differentiation exists. Thus we have found that sugars and thiocyanate enter throughout the whole of the circumference of the posterior segment while sodium and chloride enter in significant quantity only from the ciliary region. This, as we shall see presently, is important, but in the meantime we may note that in the posterior segment not only is the barrier less permeable and more selective, but for some substances, such as salt, is regionally selective.

Let us compare this with what happens in the body generally. As a working concept the capillaries may be considered as a meshwork of thin, platelike endothelial cells placed edge to edge to form a mosaic, the opposing edges being made tight by an intercellular cement substance of calcium protein-

ate, except for the presence of pores. In the extremities the tissue fluids contain some 0.5-percent protein; in the liver and intestines, 50 percent of the plasma proteins escape; in the intraocular fluid (and in cerebrospinal fluid) there is only a trace (0.02 percent). We may take it, therefore, that there are some pores in the intercellular spaces of the capillaries of the extremities of a diameter up to 38 Ångstrom units (the equatorial diameter of the plasma proteins); a large number in the liver and intestine; and only an exceptional one of this size in the capillaries of the eye. In the body generally, however, molecules smaller than this pass through the intercellular spaces of the capillary walls with ease—sodium, potassium, chloride, nitrate, and urea almost as easily as water, calcium, magnesium, and glucose with only slight delay—and even such large molecules as inulin comparatively easily. That is a physical passage by diffusion mainly through inactive intracellular spaces. The delay experienced by all molecules in traversing the ocular capillary walls and the differential retardation of molecules on a chemical basis can only, I think, be reasonably explained by a transference essentially through cell bodies instead of through their interspaces. This, of course, is not dialysis but something more subtle, discriminating, and apparently purposive.

A word now as to the regional differentiation. The blood-aqueous barrier in the anterior segment must be the uveal capillaries. In the posterior segment of the eye we have seen that there is a greater over-all difficulty in transit, more chemical differentiation, and in particular the block to sodium and chloride is very effective. We know that, when the retinal arteries are blocked, the inner layers of the retina behind the equator die, but anterior to the equator the entire thickness of the retina can be nourished and maintained in health from the anterior ciliary vessels. The deduction we may tentatively draw from this is that in the posterior segment of the eye, transudate from the choroi-

dal capillaries does not reach the inner retinal layers, in quantity at any rate, so that fluid traffic into the vitreous in this region is essentially from the retina; in the pre-equatorial part of the vitreous chamber, on the other hand, traffic will be from the retina and choroid; and in the most anterior part, from the ciliary body. Posteriorly, therefore, where only the tenuous internal limiting membrane of the retina separates the tissues from the ocular cavity, the nature of the fluid bathing the vitreous will be determined essentially by the retinal capillaries.

This opens up a very interesting analogy between the permeability of the capillaries of the retina and those of the central nervous system. We know that all the capillaries of the body except those of the central nervous system are stained by acid dyestuffs such as trypan blue and allow their passage freely through their walls. Palm has recently shown that the same peculiarity applies to the retinal capillaries, for neither the endothelium of these capillaries nor the tissues of the inner retinal layers take on such a stain. It is obvious that the block here is the capillary walls. It is also interesting that the same deficiency of sodium chloride is found in the cerebral tissue-fluid as we have found in the vitreous. It would seem that the retinal capillaries have the marked peculiarities of the capillaries of the central nervous system which have been shown to differ widely from those of the rest of the body.

Let us turn now for a moment to the concentration of the various constituents of the intraocular fluid. It is interesting that all its constituents are in deficit in comparison with the plasma with four major exceptions: (1) hyaluronic acid, which must be synthesized locally and secreted into the eye; (2) ascorbic acid, which in some species (including man) seems to be actively transferred from the blood to reach a high concentration in the aqueous; (3) lactic acid in the presence of the lens, presumably a metabolic product; and (4) salts. The excess of salt (sodium and chloride) in the aqueous in comparison

with the blood is, I think, real. I am aware that this has been questioned, but our chemical analysis has received confirmation from another point of view. By every method we have employed we find constantly that the osmotic pressure of the aqueous is higher than that of the blood plasma; and if the two are dialyzed across a collodion membrane, chemical and physical measurements show a transference of salt from the former to the latter. It seems, therefore, that while all other freely diffusible substances with the specific exceptions just mentioned are in deficit, the concentration of osmotically active salts in the aqueous humor is in excess of that in the blood: in its transfer energy must therefore be expended, that is, it must be secreted.

Studies of the most varied nature in other organs of the body have consistently failed to produce any evidence that the capillary walls act otherwise than as a simple filter; they may block substances but they have not, so far, been detected in the act of secreting any substance. We know that, in the posterior segment, salt enters essentially in the ciliary region, and the work of Friedenwald, so ably summarized in his recent Proctor lecture, suggests a mechanism which might form the basis of such an active process occurring in the ciliary epithelium.

In the formation of the intraocular fluid we are therefore led to the suggestion that throughout the vascularized tissues of the eye there is a peculiar and controlled transfer of materials through the cell bodies of the capillaries instead of through their interspaces as in the body generally, and superimposed upon this, presumably in the ciliary region, a secretion of osmotically active salt. It is quite possible and indeed probable that the ciliary secretion may embrace other substances than salts, but I know of no conclusive evidence as yet to prove this.

If the integrity of the capillary walls is impaired, of course, these conditions are immediately and fundamentally altered. This change, which occurs universally throughout the capillaries of the body, can be accom-

plished by toxic or chemical influences but is most easily seen in alterations of the pressure relationships. This property of capillary fragility (as opposed to permeability) can be seen if a capillary is closed at both ends and is injected under pressure with India ink by means of a micropipet; as the pressure is increased the India ink will spurt out through a few isolated spots between the epithelial cells even though no tears in the endothelium can be seen. When the pressure is reduced and the circulation allowed to resume, these particles remain as localized collections outside the capillary walls and flow is resumed with permeability unimpaired. On paracentesis of the eye the reverse pressure relationship is seen, for the sudden lowering of pressure outside the capillary walls allows the passage of a protein-rich fluid wherein all the diffusible constituents approximate those of the plasma to form the plasmoid aqueous humor which is a simple filtrate from the blood; the proteins and all the diffusible substances increase, except the chlorides which diminish. In this case the ocular capillaries revert to the mechanism of the capillaries generally, and about this mechanism, which is universal throughout the body, we need not concern ourselves further.

Let us turn now to the drainage of these fluids. From experiments with heavy water, first carried out by Kinsey, Grant, and Cogan in Boston, we know that there is a full and free transfer of water in both directions across the capillary walls, just as occurs throughout all the bodily tissues, determined by the kinetic energy of the molecules involved; half the aqueous of the rabbit, for example, is replaced every 2.7 minutes—that is, there is a transference into and out of the anterior chamber of about 50 cu. mm. per minute. In addition to this there is a through-and-through circulation by way of the canal of Schlemm and the aqueous veins. This, unlike the general metabolic interchange, is not a process of diffusion but an undifferentiated flow in bulk allowing free mechanical exit to com-

paratively large molecules. This has been shown experimentally in my laboratory and also by a number of investigators using various techniques, and has been confirmed by the observation of the exit-flow through the aqueous veins in the human eye; the unanimity obtained by these results is striking. It would appear that in the normal eye approximately one percent of the fluid in the anterior chamber drains away per minute, a flow amounting in the normal human being to some two cu. mm. per minute.

We have now come to the point when we might venture to clothe these facts with some integrative philosophy. It may be asked, what is the purpose of this relatively complicated mechanism which we are postulating? Presumably it is concerned with making the eye a useful optical organ for which purpose two desiderata are necessary— optically clear media and an internal pressure sufficiently high to keep the globe a relatively rigid optical system. The peculiar impermeability of the ocular capillaries can be construed as a teleologic adaptation to maintain the ocular media optically clear and homogeneous. Transparency is maintained by excluding substances from the aqueous, but the deficiency of sugar, urea, creatinine, amino acids, and proteins amounts to about 4.5 millimols per liter. This has to be made up. An essential function of salts in the body is to maintain osmotic flow and equilibrium throughout the tissues. By a secretion, containing among, perhaps, other constituents, salts, this is made up and more than made up, so that the pressure in the eye is determined as a hydrodynamic steady-state by the capillary pressure plus an excess of osmotic pressure. And a slow outflow is provided, allowing a leak at the angle of the anterior chamber, so that the actual pressure in the eye is less than this pressure-head; and a safety-valve mechanism is provided so that the pressure does not get out of hand.

Finally it may be useful to consider what may be the practical bearing of this on the variations of the intraocular pressure found

clinically. Obviously it may be disturbed by at least four factors: (1) An upset of the secretory activity involving in the first place osmotic changes; (2) a change in the permeability of the capillaries allowing the formation of a filtrate; (3) a change in the hydrostatic blood pressure, becoming effective either at the arterial ends of the capillaries when a rise in blood pressure will involve a rise in ocular tension or in the venous capillaries when an increased flow will encourage reabsorption of fluid and bring about a fall of ocular tension; and, finally, (4) by a blockage of the drainage channels which, by embarrassing the safety valve, will lead sometimes to a cumulative rise of pressure, sometimes to a strangulating crisis depending on other events in the eye.

About the effects of an upset of the secretory mechanism we know nothing; that is a problem full of enticement but equally full of difficulty. About the effects of vascular disturbances we know more. So far as local events are concerned, the effects of a rise in the capillary pressure on the tension of the eye have been elucidated. We also know that local stimuli have a generalized vasodilatory effect throughout the entire uveal tract through the mediation of axon reflexes so that dramatic results may follow insignificant stimuli. The massive and widespread vasodilatation, associated with increased permeability and edema, that may result therefrom constitutes the picture of acute congestive glaucoma. We also know that an increase of flow through the venous capillaries tends to lower the intraocular pressure; this action of eserine and pilocarpine, which cause such a dilatation and even open out new functional capillary districts, I think accounts for their hypotensive action often as much or sometimes more than their mechanical miotic effect. But about the central control of the local vascular system we know much less. Clinical observations with, it must be admitted, a slender experimental background suggest that neurovegetative, endocrine, and psychosomatic influences play an important part in its regulation; and

clinical and experimental facts relating to the diurnal pressure variation, the existence of a regulating mechanism, and the interdependence of the circulatory events in one eye with those in the other, whether determined by chemical or mechanical stimuli, strongly suggest the presence of a controlling center in the central nervous system, presumably in the upper brain stem or hypothalamic region; but the whole of this subject awaits experimental exploration.

About the effects of deficiencies or difficulties of drainage we are more fully aware; and probably because they are more obvious and amenable than the others to dramatic relief by treatment, I think we often attach undue importance to them. We know that a blockage of the angle of the anterior chamber seems frequently to be a precipitating cause of an acute congestive glaucoma. But it is equally important that a similar crisis may occur with the angle open as is seen, for example, in acute hypertensive uveitis. In this condition, if the accompanying vasodilatation and edema can be mitigated by control of the inflammation, the tension may fall. And after operation the tension may fall even though the angle, both in the operative area and elsewhere, is still gonioscopically blocked, suggesting that in some cases the hypotensive action of surgery may act by cutting short a vascular crisis rather than by opening up new drainage channels.

Similarly, in simple glaucoma we suspect that in a large number of cases there is some subtle hindrance to the exit channels of the intraocular fluid. But at the same time, in this disease, the outflow through the aqueous veins may be apparently at approximately the normal rate. Moreover, our everyday experience, that the normalization of pressure, either pharmaceutically or surgically, frequently does not prevent the evolution of the symptoms of this disease in their characteristic remorseless course, points to the fact that the whole philosophy of such cases cannot lie within the confines of the angle of the anterior chamber. Blockage of the drainage channels is certainly an adjuvant factor, but other mechanisms are as certainly operative; and these still require much exploration. For example, the state of capillary instability, found so commonly in cases of simple chronic glaucoma, and the lack of vascular compensation in conditions of stress, as seen in some provocative tests, are suggestive of an underlying fault in the capillary circulation, perhaps the same underlying fault which at the angle and the optic nervehead determines sclerotic changes.

The danger, of course, in studying so vast a problem is that in trying to unravel its intricacies we tend to become so specialized, each in our particular pursuit, that a broad and comprehensive view of the whole becomes increasingly difficult. Vascular events monopolize the attention of this investigator, the angle of the anterior chamber of that other. Such indeed is the tendency with the ever accelerating growth of ophthalmology in all its aspects—and indeed of all knowledge. Twenty-five years ago life was easy; today the physiologist, the chemist, the physicist, the mathematician, and the clinician all jostle each other in the market place, each advertising his own wares in his own peculiar language. To make advances in knowledge, specialization on minutiae is undoubtedly necessary; but we must beware lest, in the expanding sphere of thought, each individual discipline moves steadily away not only from a unifying and coördinating philosophy but from cognizance of each other, so that the value of each is vitiated by the exaggeration of its devotees, and its contribution to the solution of the problem as a whole is lost. For the subject of this lecture a comprehensive solution is yet far away, but insofar as it is an attempt to integrate some aspects of the problems concerned, it may perhaps be not without some value.

63 Harley Street (W.1).

CIRCULATORY ASPECTS OF THE GLAUCOMA PROBLEM*

The Second Mark J. Schoenberg Memorial Lecture

JOHN N. EVANS, M.D.
Brooklyn, New York

The opportunity to deliver the second Mark J. Schoenberg Memorial Lecture brings to me a double honor. First, is the privilege to pay his memory respect; second, the privilege of associating my name through all time, not only with his, but also with all those who by these lectures perpetuate his accomplishments. His greatness of character has touched with stimulating effect all who knew him.

It is my purpose to discuss certain mechanical aspects of ocular circulation, which it seems to me can be brought together at this time not only because they include phases of our work in which Dr. Schoenberg was interested, but also because an effort is now in progress, through national and local committees[†] to assemble many of the loose ends which may help us to a clearer view of the symptom complex which we call glaucoma.

It is proposed to discuss phases of problems which have come to my attention through my own and my colleagues' ordered studies.

One must not lose sight of the fact that the word "circulation" may not refer solely to that of the blood-vessel system. It has been employed in referring to lymphatic channels and by Cushing,[1] under the heading of "the third circulation," to describe the cerebrospinal-fluid system.

There is a similarity between the cerebral and intraocular-fluid circulations. The word "circulation" in this sense is, of course, used broadly and was thought by some to be more comparable perhaps to the ebb and flow of a tide, its movements varied by depletions and excesses through tissue demands. Modern studies were necessary to prove a continuous flow from source to outlet.

The intraocular fluid has, to my mind, a major and a minor circulation. The lesser circulation is that of the aqueous chamber, the greater that of the vitreous. Combined they may be called "the fourth circulation."

I suspect the aqueous metabolic interchanges are less massive, although there may possibly be a greater rate of flow than there is in the greater circulation. I believe we should think of the vitreous as dynamically active. We might call it the liver of the eye because of its diverse storage of metabolites.

Perhaps the physiologic course of the fourth circulation would be: arteries through capillary endothelium, to aqueous and vitreous chambers, then posteriorly through the perivascular drainage spaces[‡] and anteriorly through the escape exit of the canal of Schlemm, both to mix with venous blood.[¶]

It is conceivable that the posterior perivascular drainage may mingle with the cerebrospinal fluid of the vaginal space but our data for this idea seem to be insecure. There is evidence that certain bodies are

---

† The work of the committee on standardization of tonometers; the work of the committee on the classification of the glaucomas; various tonometer testing stations; establishment of numerous glaucoma clinics.

‡ Priestly Smith[2] established that 2 percent of the outflow was by the posterior route. It would seem to me that 75 percent would be more reasonable in view of our modern ideas of vitreous function as a storehouse for retinal fuel and possibly waste products.

¶ It would seem probable that the vitreous may even receive certain of its constituents from the choroid. This is obviously so in pathologic studies, when we note opacities of the vitreous associated with the appearance of choroidal lesions.

passed from vitreous to orbital tissue. The question of the ultimate avenues of posterior drainage is definitely controversial. The metabolic constitution of fluid at any point in the fourth circulation would, of course, show local variations as it does in blood in accordance with local supply and demand.

Such an apparently static nutrient and waste concentration might indicate that the fourth circulation is designed only as an accessory for tissues of a low metabolic rate but we know that this is, in an overall sense, not so.

The interrelation of glucose interchange of vitreous and retina alone indicates that it may function as part of the retinal nutritive activity.[3] We realize that the actual volume of retina having a high metabolic rate is supplied on its outer face by the active blood bed of the choriocapillaris and that its inner face is also in contact with a relatively greater volume of vitreous.

The characteristics of a reversible elastic gell permit fluid transfer. This indicates that material amounts of nutrient and waste can be interchanged between retina and vitreous. The posterior drainage could thus be more active than past workers have indicated.[4] We need not discuss the properties of the vitreous as a gell and its many metabolic functions. Such studies have not been included in my own investigations.*

If we ask ourselves what are the metabolic demands placed upon the aqueous humor, we must admit that our answer is hypothetical. The cornea receives some benefits in a nutritive sense but the circumcorneal vessels must be a major supply source and there is a material absorption of oxygen through its exposure to the air. The iris, having its own vascular system, is relatively independent in maintaining its own support. All points considered, it would seem that the vitreous

or greater portion of the fourth circulation should receive more attention. I should like to refer to a feature of vitreous structure which may even be quite active physiologically, and more active when pathologic conditions arise, I refer to fluid interchange.

The embryonic system of vessels, which is normally observed before birth, leaves behind infinitely fine fiber strands, that may be looked upon as cleavage planes or avenues of interrupted vitreous continuity. Experiments conducted by me in 1931[5] were suggestive that certain stains injected into the retrolental space were carried from the eye through the perivascular space† regions of the optic nerve and that they passed through the vitreous along lines strongly suggestive of the idea of fiber strands, cleavage planes or channels.‡ This impression is also gained in those cases of rupture of retinal veins when we see an irregular funnel-shaped formation of the escaped blood from an apex at the disc outflaring toward the lens. Active hyalitis sometimes shows a similar arrangement of inflammatory products and also is suggestive of orderly escape paths.

Mere cleavage planes of lessened resistance through the vitreous would suffice for the flow of fluid, the migration of mobile tissue cells, or even for the direction of growth of newly formed vessels.

Our present interest lies in the possibility that under pathologic conditions, the aqueous element of the vitreous might be gradually increased in the deeper parts of the gell, to be released by relatively sudden gushes

---

* The gell properties of the vitreous, particularly its changes in volume in response to fluctuations of the acid-base balance, have, in spite of elaborate studies, not advanced our understanding of the mechanism of intraocular pressure changes.

† My studies were made on animals[6] and human beings.[6] The literature dealing with our understanding of posterior drainage was published in 1930.[23] It gave credit to other workers for ideas similar to those presented at this time.

‡ I appreciate that when the acid-base balance of the vitreous is artificially disturbed, fibrillar micella[7] appear, with their long axes at right angles to the posterior lens capsule. We can confine our consideration to vitreous of undisturbed chemical balance, however, and still find evidence of retinal vessel strands. All other experimental methods of studying posterior drainage flow would seem to lead to false conclusions.[8]

through the cleavage planes to the perivascular lymph spaces which drain through the optic nerve.

This condition, with high pressure, can arise in the presence of relatively normal appearing vitreous which is relieved by a gushing forth of fluid and has been seen by all of us when performing a posterior scleral trephination.

As the opening is completed, a very considerable amount of fluid may eventually spurt from the vitreous chamber followed by the appearance of the apparently healthy gell. One can assume that, when the posterior drainage mechanism is obstructed, the iris-lens diaphragm advances, giving rise to the picture of shallow-chamber glaucoma.

The fact that the vitreous vessel remains sagged downward in adult life, would add to, rather than detract from the idea. The influence of gravity on the dependent regions of the vitreous would encourage a pool of the aqueous element below and would require a more elaborate system of escape than would the superior regions of the vitreous.

The vitreous is, according to Duke-Elder,[9] normally in its maximum stage of turgescence in healthy eyes and we must realize that gells act relatively slowly in transmitting water from one region to another. If this is so, acquisition of aqueous must be balanced by an equal escape and, since capillary dilation means increased permeability, we realize that the entire mechanism must be in constant activity.

Large nutritive demands upon the vitreous, although intimately related to similar demands upon the retina, are exceedingly difficult to study or demonstrate. The possible relation of vitreous volume to choroidal volume may seem more obvious.

The choroidal blood bed, representing as it does a much greater volume than the retinal, projects its dynamics into the problem of glaucoma. Moreover, we think of the choroid as a loosely woven mesh of thin-walled vessels in a pialike reticulum which

is so designed that there is little structional restraint on active dilation and contraction of the vessels. It is even possible that the scattered muscle fibers of the choroid may be able to modify the gross thickness of the choroid as a whole. On the other hand, blood volume in the choroid may be varied by systemic changes or by a locally acting mechanism.[10]

It has long seemed to me that we gain a very artificial picture of the form, and hence the functions, of the choroid by the study of the usual histologic preparations. An uncompleted investigation into this question has lent evidence to indicate that the relatively thin appearance of the choroid, which we study microscopically, is in part due to the fact that the standard techniques of enucleation drain most of the blood from the eye.

To demonstrate this, a study was performed on a number of cats and monkeys.*[11] One eye of each animal was enucleated by obstructing the escape of blood of all vessels by the use of the actual cautery or by ligation. The technique was so successful that the orbits after enucleation were perfectly dry and there was no evidence of escaped blood on the globe. The fellow eye, used as a control, was enucleated by the usual technique of dividing tissue and vessels with scissors and scalpel. Both eyes were immediately placed in formalin for fixing and the usual and identical technique was applied to each eye in preparation for histologic study.

The thickness of choroid was measured in cauterized and control eyes only in the region where the macula was visible in the section and where the structures had not been torn or disarranged by the microtome. This precaution was taken in order to be sure that comparable regions of the choroid were measured for thickness.

To cite one example, the eye of a Sooty Mangabey monkey was studied. The average

---

* Rhesus and Sooty Mangabey monkeys.

measurements of the thickness of the choroid at the macula in four sections of the control eye, as measured with an ocular micrometer were 0.18, while the average thickness of four cautery-enucleated eyes was 0.273.* Thus, the choroid of the eyes removed without blood loss was 50 percent thicker. Moreover, the larger choroidal vessels were more rounded in cross section than oval, as is usually seen.

It is obvious that such a study is far from flawless in many respects. Yet its implications seem significant. In the living eye, the choroid must be much thicker than indicated in any of our preparations. A relatively drained choroid, as compared to a turgescent choroid, would represent a very great difference in the volume of the intrascleral chamber between these extremes.

A sudden depletion of the choroidal blood bed would be accompanied by a compensatory increase in volume of the vitreous through acquisition of the aqueous element. If this compensatory effect were over-sufficient, a rise of ocular tension would result but only if there was a derangement of the posterior drainage system. We must consider whether such violent variations of choroidal thickness can occur.

The interrelation of the clinically plotted[24] angioscotoma and the mechanism of the perivascular-perineural space has been a help in directing the management of glaucoma cases. Plotting the macula wedge as an index to prognosis and time of operation has been particularly helpful. It would seem reasonable, therefore, to conclude that there is modern evidence for the presence of a posterior drainage exit to support the incomplete evidence of the past.

After considering these features relative to the major division of the fourth circulation, it might seem reasonable to concentrate, in the future, on its physiology as an approach to the many problems of glaucoma.

---

* These are units of the ocular micrometer and do not refer to millimeters.

It would be well to accept the idea of a "posterior" and an "anterior" glaucoma rather than to rely on a foreign differentiation of deep- and shallow-chamber glaucoma. We would do well to consider a specific and separate pharmacology for the posterior-chamber type; especially would it be well to consider those agents which modify, the caliber of the uveal and retinal blood vessels.

A logical surgical technique for this type of glaucoma should be devised.[†] Surgical measures may involve the production of a minute area of choroidal atrophy by the application of beta rays, radium, or the thermophore, followed by a small scleral trephination with conjunctival flap over the atrophic area.

The blanching of the skin capillaries and the cerebral vascular changes occurring with emotional shock might conceivably be associated with similar changes of the choroidal vessels. In fact, Cholst[12] has presented experimental evidence of violent circulatory changes in the eye under shock conditions. These alterations provide a possible explanation for volume changes in the vitreous chamber. They might conceivably give rise to those attacks of acute glaucoma which are often associated with acute nervous shock.

Such ideas, of course, are highly speculative in spite of the oft-used phrase "sympathetic hormonal mechanism" and our generally accepted recognition of the fact that nervous shock often precipitates acute attacks. Repeated minor disturbances of sudden choroidal thickening with an inadequate posterior drainage might conceivably be the background for a chronic glaucomatous state.[‡]

---

† It is interesting to note that the first successful effort toward the permanent surgical relief of hypertension was made by William Mackenzie (1830), who believed that vitreous changes influenced the site of increased pressure.

‡ The fact that appropriate fluids, deposited experimentally in the anterior vitreous, pass out of the eye through the posterior drainage system in 3 to 4 minutes (my own studies) may possibly have significance.

More detailed study of the choroidal vessels may shed more light on how this turgescence and depletion are brought about. In a group of studies conducted for a different purpose, a so-called capillary sphincter muscle was described.[10] Other workers[13, 14] have shown that like muscles in a number of tissues relax and contract under the effects of therapeutic agents.

We have shown histologic surface preparations suggesting that spasm of such capillary sphincters, when maintained over a long period of time, results in the formation of permanent strictures with greatly distended capillaries. These capillary sphincters have no relation to the hypothetical Rouget cells studied by Krogh.[15] In fact, many modern authors contend that Krogh's work cannot be duplicated. Moreover, the endothelial cells of vessels of the order of capillaries probably cannot swell and shrink[16] enough to modify greatly the volume of the capillary bed.

The passive injection and depletion of the immense choroidal capillary bed is thought by some to be controlled entirely from the arterial side in conjunction with venous activity of similar nature. In any event, the crux of the mechanism deals with the nature and force of capillary blood flow. The difference in the pressure gradient is sometimes accepted as an adequate explanation of capillary blood flow.

This question of forcing a fluid of relatively high viscosity through tubes as small as the capillaries* is not only debated by students of human physiology but also by students of plant physiology who are still trying to explain the origin of the terrific force which causes the sap to rise hundreds of feet to the tops of trees. It would seem, therefore, that a local mechanism is present which could conceivably give rise to sudden or gradual capillary distention and result in increased thickness of the choroid.

The history of efforts to define the form

and functions of the perivascular spaces of the retina and optic nerve has been outlined elsewhere.[5] One is impressed with the similarity of these early studies to the efforts of the neuro-anatomists to investigate the cerebral perivascular spaces. At first, all was a confusion of artefacts created by techniques which were little understood.

The simple definition of the retinal perivascular spaces was, to my mind, first accomplished by the reliable technique of Wegefarth, one of Harvey Cushing's associates. He used a Prussian-blue method[17] which was radically different from the Prussian-blue methods previously employed.[†18]

Held[19] succeeded in devising a special stain and technique whereby he was able to study the minute histology of the cerebral perivascular spaces, and Kruckmann,[20] working in association with him, apparently accomplished the same result for the retinal spaces. As far as I know, however, Kruckmann's work has not been duplicated. In spite of this lack of corroboration, it is likely that his interpretations are correct. It has been pointed out elsewhere[22, 23] that there is other clinical and pathologic evidence of the existence of retinal perivascular spaces, and for other aspects of vitreous function.

Plotting of angioscotomas in all their physiologic and pathologic manifestations[22] has now been repeatedly duplicated by many workers all over the world. It would, therefore, seem justifiable to accept the hypothesis by which the studies were interpreted as reasonable. That hypothesis postulated primarily a perivascular space relation and an ultimate interruption of the retinal synapse.

CONCLUSIONS

1. The intraocular-fluid system may be looked upon as a fourth circulation (1. vas-

---

* On occasion so small as to permit only a single red cell to pass.

† I attempted to duplicate the technique of all earlier workers but my own studies of the retinal perivascular spaces confirmed the findings of Wegefarth.[17] Moreover, other workers (Magitot, Bailliart) have found obstruction to the retinal flow due to periphlebitis.[21]

cular; 2. lymphatic; 3. cerebrospinal fluid [Cushing]).

2. The vitreous may take a much more active part in the nutrition and in the pressure regulation of the eye than has heretofore been realized. There may be a large variation in the amount of the aqueous element of the vitreous during emotional shock and in general physical states.

3. The rapid passage of the aqueous element of the vitreous is probably greatly facilitated by "cleavage planes" within the substance of the vitreous. These cleavage planes or channels are the remnants of the embryonic vitreous vascular system.

4. There is considerable evidence to support the idea of a highly efficient and active posterior drainage system.

5. Marked variations in the volume (thickness-cross section) of the choroid can take place under a wide variety of conditions of systemic and local origin. Such variations, in the presence of obstructed posterior drainage, are capable of causing violent and rapid rises of intraocular pressure.

6. The capillary sphincter "muscle" of the uveal blood vessels provides a local mechanism which may be responsible for rapid changes in choroidal volume under general physical and psychologic stimulation.

7. These conceptions, supported by a great mass of experimental evidence, help to explain posterior (shallow-chamber) glaucoma and indicate the need for especially designed pharmacologic and surgical measures.

GLOMUS CELLS IN THE HUMAN CHOROID AS THE BASIS
OF ARTERIOVENOUS ANASTOMOSES*

Arnold Loewenstein, M.D.
Glasgow, Scotland

Harvey's thesis that the blood circulates from artery through capillaries into the veins is still the basis of our knowledge, although the last decades have shown that this truth is not without important exceptions. It has been known for 70 years at least (1877) that local short circuits may exist between artery and vein, which eliminate (more or less) the capillary system. So strange did this appear at first, that such an authority in the sphere of vessels as Thoma of Dorpat declared, in 1892, permanent arteriovenous anastomoses to be theoretically impossible, and Mall (1906) added that they would mean catastrophe if they should exist.

The careful investigations of Hoyer (1877), Grosser (1902), and Von Schuhmacher (1904), however, have proved that arteriovenous anastomoses exist physiologically in certain animal tissues, and that they can be opened and closed. Thus the blood stream takes the capillary path when the short circuit is closed, or runs through the opened arteriovenous anastomoses directly from the artery into the vein (figs. 1a and 1b). As a rule, the lumen of the arteriovenous anastomoses is changed quantitatively but efficiently, and a complete closure does not occur.

These arteriovenous anastomoses at first were virtually ignored by anatomists, physiologists, pathologists, and clinicians. Then, interest was aroused by the initiative of Hans Hawlicek, a surgeon, who realized the great importance of this double blood circulation.

Arteriovenous anastomoses were soon the object of careful research, the classical papers being by Clara (1927), Spanner (1932), Clarke and Clarke (1934), Masson

(1935). Only the most important papers by these authors are quoted.

Arteriovenous anastomoses were found in many animals.
Fig. 1a (Loewenstein). The blood stream takes the capillary path when the short circuit is closed.
Fig. 1b (Loewenstein). When the anastomosis is open, the blood stream runs directly from the artery into the vein.

Fig. 2 (Loewenstein). Glomus cells in the arterial walls of a normal choroid. (Hematoxylin-eosin. ×300.)

In man, they were discovered in the pulp of the fingers and toes, the nailbed, the corpus cavernosum of the penis, in the glomus coccygeum, the villi of the intestine, and in other tissues. Masson associated the normally present arteriovenous anastomoses of the fingers with painful small tumors, enveloped in a rich muff of myelinated and nonmyelinated nerve fibers, which he called "glomus neurovasculaires" (1937).

The cells which are responsible for the mechanism of arteriovenous occlusion are of an epithelial character, and are placed external to the endothelium. They are found frequently in 4 to 5 layers, and are of very characteristic microscopic appearance. They are sharply outlined, the cytoplasm is clear, the nucleus is round and central. No membrana elastica interna is seen in the arteriovenous anastomoses.
Fig. 3 (Loewenstein). Glomus cells in arterial wall of the choroid in a hypertensive case. (Hematoxylin-eosin. ×300.)

Although the arteriovenous anastomoses are more frequent in old people, Masson has found them in the fetus of 4 to 5 months, and in the newborn.

We are indebted to Clarke for the introduction of a technique permitting continuous observation of the living arteriovenous anastomoses under high magnification by a glass chamber implanted in the rabbit's ear. The Clarkes thus discovered independent

in the middle and outer choroidal layers.

These cells (fig. 2) are polyhedric or round. In diameter they are between 10 to 20 μ. sharply delineated, with a smooth, evenly dark-stained cellular membrane. They have a strikingly clear cytoplasm. The nucleus is central, darkly stained by hematoxylin, and without a visible nucleolus. Where these cells are found in groups they appear closely attached to each other, divided by the sharp

Fig. 4 (Loewenstein). Fatty, swollen endothelial cells in an atheromatous choroidal artery. Here the nuclei are granular, pale, and most eccentric. Note the granular cytoplasm. (Hematoxylin-eosin. ×300.) (A) Hexagonal cells. (B) Bruch's membrane. (C) Choriocapillaris.

spontaneous contraction and dilatation of the arteriovenous anastomoses, which is faster than the arterial. The rate of contraction is different in arteriovenous anastomoses of close vicinity. Dilatation is as rapid as contraction.

Their autonomy is apparent and places the arteriovenous anastomoses into a special category in the whole circulatory system. Masson compares them anatomically and physiologically with the heart.

So far, arteriovenous anastomoses have been discovered in a restricted number of tissues only. I have observed, in the choroid of both normal and pathologic eyes, large clear cells of a certain uniformity. They were present in groups of medium- and large-sized choroidal arteries, and therefore

cellular membrane. Their whole appearance is reminiscent, in fact, of epithelial cells (fig. 3).

I have found them in choroidal routine, celloidin sections stained with hematoxylin-eosin, in Van Gieson, Masson, and Mallory stained slides. They are invisible in Weigert's elastica staining. They are located in the posterior pole area, and are absent in the anterior choroid.

I have also seen them in the intrascleral part of the posterior ciliary arteries of normal eyes. Their frequency is greater in hypertensive cases (fig. 3). They were especially rich in the posterior part of the choroid of an eye in which a metastatic malignant growth in the orbit pressed on the posterior portion of the sclera.

This histologic picture is very striking. The only pitfall might be the presence of huge swollen endothelial cells in choroidal arteries, the so-called pseudoxanthoma cells, in cases of malignant hypertension. But this "clear" cytoplasm is granular, the nucleus is pale and eccentric. Fat staining makes the differentiation complete (fig. 4).

The cells described correspond to those depicted by Clara, Spanner, Masson and others, and are called "glomus cells" or "epithelial muscle cells." I am unable so far,

Some of these vessels with epithelial muscle cells have an inner elastic membrane; others have none.

Epithelial muscle cells are found at a
Fig. 6a (Loewenstein). Choroid in flat, Mallory stain, oil immersion. A rich mass of glomus cells in the wall of an artery. Difficult to distinguish between small, smooth muscle cells and epithelioid muscle cells.

however, to reconstruct a complete picture of a clear-cut arteriovenous anastomosis with its arterial source, with the short circuit and the vein, like many of the other investigators of arteriovenous anastomoses. Technical difficulties vary in different tissues.

The glomus cells, both single and grouped, are visible in the sagittal sections of the choroid of the macular area, which has been embedded as flat as possible in celloidin, and sectioned in this way. The glomus cells are especially frequent where the arteries are tortuous and change the breadth of the lumen abruptly, sometimes from 1 to 4 μ (fig. 5).

Fig. 6b (Loewenstein). Choroid in flat, hemalum, oil immersion. Epithelioid cells.

certain distance from the endothelium, which itself is lined with the empty shells of cells (figs. 6a and 6b). These cells might be the circular smooth muscle fibers, cut eccentric to the nucleus. On the other hand, I am not sure whether these shells do not belong to eccentrically sectioned epithelial muscle cells.

The exact relationship between glomus and smooth muscle cells has not been determined so far. In the choroid both cell types might occur intermixed.

I have tried to find the structure of the arteriovenous anastomoses in choroid in bulk. For this purpose, the macular area of the choroid is first depigmented with potassium permanganate and oxalic acid; then the specimen is stained with a dilute hemalum solution for 24 hours and cleared in glycerin. The rich mass of nuclei is rather disconcerting and no counter staining therefore appears indicated.

In this way I was able to discover several groups of epithelial muscle cells (figs. 7a and 7b). They are grouped round a cystic empty space. The cells are of varying size, mostly polyhedric, sharply outlined; the cell membrane is sharp. Delineation between the single cells is well marked. The nuclei are dark, round, and generally central. These epithelial muscle cells stand out distinctly against the background of the smooth muscle fibers of the arterial wall. In a few instances only, there are more nuclei of the type described in a big cytoplasm, without being separated by cellular membranes.

These cells are at various depths—therefore the prospects of photomicrographic reproduction are poor. The dense background of nuclei adds to the photographic difficulties. These cell groups are similar, indeed, to all that has been demonstrated of arteriovenous anastomoses previously.

Generally, we must expect to recognize histologically the large dilated glomus cells only, while the contracted ones are oblong or spindle-shaped. There is little hope of identifying the latter two shapes in a stained
Fig. 7 (Loewenstein). Choroid in bulk, macular area, depigmented, hemalum, 24 hours, ×300, seen from scleral side. (A) Epithelioid muscle cells surrounding a cystic space. (B) Smooth muscle fibers of a middle-sized choroidal artery.

bulk specimen. But even in sections, I was unable to discover anything apart from the epithelial form of the glomus cell. We have found, therefore, a part only, and possibly a small part, of the motive mechanism of the
Fig. 8 (Loewenstein). Choroid in bulk, depigmented, teased, hemalum, 24 hours, ×300. One middle-sized choroidal artery shows narrowing at X. The muscle cells are dense, bigger, and darker at the place of contraction. A broad ciliary nerve branch crosses the vessel.
Fig. 9a (Loewenstein). Retina in bulk. Hemalum overstained and cleared. ×300. Sphincter contraction of branches. Note ganglion and glial cells in the superficial retinal layers.

choroidal blood circulation. That includes all previous research as well.

The investigation of the bulk choroid was continued by teasing the stained choroidal tissue with two needles, and clearing the shreds with glycerin.

I found, while following the course of a middle-sized artery, that the lumen 45 to

Fig. 9b (Loewenstein). Hypertensive retinopathy. Bulk specimen, hemalum, 24 hours, ×150. Sphincter contraction at the branching place of arterioles. Note retinal ganglion and glial cells.

50 μ diameter, narrowed down for a short distance to 15 μ and dilated again to the same width of 50 μ, that is a considerable contraction (fig. 8). It is interesting to observe that the muscle cells in the contracted area are denser, bigger, and appear darker than in the dilated part. We conclude that contracted smooth muscle cells in an arterial wall appear different histologically from the unstimulated ones.

Spastic changes in retinal arteries are supposed to exist and have even been observed in progress ophthalmoscopically. But no contraction of such degree has ever been seen ophthalmoscopically.

On the other hand, sphincter contraction has been described by Evans (1947) as an abrupt narrowing of certain retinal capillaries where they joined the vessel of the next order. I have shown this phenomenon at the Oxford Congress (figs. 9a and 9b) in retinal bulk specimens stained with hemalum.

The same sphincteric contraction is visible in the choroid (fig. 10) in bulk specimens. Blood transport in the district of arterioles,
Fig. 10 (Loewenstein). Choroid in bulk, hemalum, 24 hours, overstained, ×300. Ring muscle fibers, no glomus cells, sphincter contraction.

metarterioles, and capillaries is far more complicated than was supposed. The brilliant investigations of Chambers and Zweifach (1946) have proved that a sphincter muscle is present at the union of a metarteriole and

an "anastomosis" (not our arteriovenous anastomoses).

I have shown at the same meeting in Oxford (1946) swollen, granular, endothelial cells in capillaries, precapillaries, and ves-

Cushion cells in Retinal Arteriole

675×
Fig. 11 (Loewenstein). Cushion cells in retinal arteriole. (×675.)

sels of unstained cleared retina in bulk at the point of branching arterioles and confluent vessels. I have suggested that these cells (fig. 11) swell and decrease, and regulate the local retinal blood supply according to need. I have not seen anything like arteriovenous anastomoses in the retina, so far.

We have seen, therefore, in the retina, two kinds of appliances to control the blood stream—the sphincter muscle and the swell or cushion cells, while we have found in the choroid epithelial muscle cells, the most probable base of arteriovenous anastomoses. The sphincter muscles of the choroidal arteries are similar to those found in the retina.

I am confident that further investigation will reveal other refinements in the regulation of the bloodstream.

It has been repeatedly stated that the choroidal structure is reminiscent of a corpus cavernosum. Filling and emptying of the biggest corpus cavernosum of man, that of the penis, is linked with existent arteriovenous of the arteriæ helicinæ.

The normal choroid is found sometimes histologically to be reduced to a thin tissue of 20 μ, while I have recorded not infrequently in the macular area of other equally normal eyes, a thickness of 200 μ.

We conclude that a regulator mechanism is able to dam up the blood and to fill the huge choroidal cavernous spaces, so impressive in flat sections or depigmented bulk specimens. It is credible, on the other hand, that arrangements are provided to evacuate this accumulation of blood in an emergency. Adaptation of the degree of filling of the cavernous system to the influx of blood and the outflow of intraocular fluid is necessary to keep the intraocular pressure at a certain level with inconsiderable and mostly regular oscillations.

One must not overlook that the most delicate tissues of the body are embedded in the hard, unyielding scleral capsule. These delicate tissues are exposed to the danger of being damaged by the increased tissue pressure, unknown mostly to soft body areas, unless a safety valve is provided. It seems that the arteriovenous anastomoses in the choroid offer sufficient possibilities to render innocuous a momentary influx of blood into the cavity of the globe. Quick reaction is therefore strictly indicated.

Such a regulation is very likely to be subject to nervous influence. Masson has, indeed, shown the highly developed and nervous muff enveloping the arteriovenous anastomoses. A similar network was shown recently by Nonidez (1942) in arteriovenous anastomoses of the sympathetic ganglion of the dog.

The nerve fiber system spread through the choroid appears very dense when studied in depigmented bulk specimens. So far, no histologic distribution of nerve fibers in epithelial muscle cells has been demonstrated successfully in the choroid. It is most probable that the function of the choroidal arteriovenous anastomoses opening and closing of the short circuits, are acting under nerve influence as are the other arteriovenous anastomoses (Clarke).

It seems different with vascular new growth in the choroid; for example, an angioma. This blastoma is seemingly not included in and subject to the free play of filling and evacuating of the blood spaces under nervous direction. We often find, therefore, increased intraocular pressure in such cases of angiomatous choroidal growth (Sturge-Weber syndrome).

It would be of great interest to observe a pulsation of the choroidal arteriovenous anastomoses resembling the spontaneous autonomous contraction found by Clarke in the rabbit's ear. I rather doubt whether the enlargement of slitlamp microscopy of the fundus will suffice. Clarke used high-power microscopy. But an eventual success will depend on the size of the pulsating area and on the intensity of the pulsation if it really exists.

There is a highly developed switchover system of the blood circulation in the tissues of the eye, basically different in conjunctiva, choroid, and retina. I have not studied so far ciliary body and iris.

The reserve vessel system in the conjunctiva has about 20 times the volume of that normally visible (Loewenstein, 1944), and will form the subject of a further paper by me. The retina, an infinitely more delicate and vulnerable tissue, has a proportionately delicate capillary mechanism in the form of endothelial swell cells, reinforced by the action of sphincters (Evans). The choroidal switchover system seems to be the most extensive.

I suspect that other devices for this purpose exist besides those described here.

Many puzzles remain unsolved and invite the investigators to continue their research in this direction. Last, but not least, it is possible that a pathologic finding might give a lead to the anatomist and physiologist. Arteriovenous anastomoses, glomus cells, respectively, are undoubtedly more frequent

in old people than in younger ones. They are found more often in hypertensive eyes than in normal ones. The process of causation remains obscure until now. It may be that their presence in the retrobulbar tumor case throws some light into the dark. More material must be collected.

I was unable, so far, to reconstruct the course of arteriovenous anastomoses from artery to vein, but I am hopeful that continued series of sections of depigmented choroidal tissue from the macular area will make it possible.

At present the first steps only have been made in this direction.

SUMMARY

Large polyhedric cells are described in the periphery of large and medium sized choroidal arteries, with a central, round, dark nucleus, a clear cytoplasm, and a smooth cell membrane. These correspond to the epithelial muscle cells or glomus cells which are the basic elements of the arteriovenous anastomoses found in several tissues of animals and man. They are present in the posterior segment of the human choroid. They occur singly as a rule, in sagittal sections, but are found linked in flat sections and are present in epithelioid units in choroidal bulk specimens.

The choroidal glomus cells were found more frequently in hypertensive cases, and were numerous in a case of retrobulbar tumor with pressure folds.

The cells form part of the ocular tissue mechanism to direct the bloodstream to the areas of need, as do sphincter muscles at the branching place of arterioles in retina and choroid and the endothelial swell cells in the retina.

Arteriovenous anastomoses appear to be the basis of the choroidal corpus cavernosum. Rapid opening and closing of these short circuits is essential for the maintenance of the intraocular pressure and is dependent on the rich nerve fiber plexus demonstrated in other glomus growth.

PANOPHTHALMITIS CAUSED BY ESCHERICHIA COLI COMMUNIOR*

RUSSELL J. NICHOLL, M.D.
Cleveland, Ohio

AND

D. LOCATCHER-KHORAZO, M.D.
New York

Escherichia coli is rarely the cause of ocular infections. Its presence in conjunctival cultures is in most instances a contamination. Eyre[1] (1897) found this organism in about two percent of cultures of normal conjunctival sacs, but in more recent studies by Khorazo and Thompson[2] (1935) it was present only three times in 1,122 cases. In rare instances it does produce inflammatory changes as evidenced by severe suppurative inflammation.

Français[3] (1935) reported two cases in which the organism was pathogenic. His first patient was a man aged 71 years, who, as a result of prostatic obstruction, developed an Escherichia coli cystitis three days following cataract extraction. A panophthalmitis occurred and the enucleated eye showed Escherichia coli. The second case was in a two-month-old child with a congenital dacryocystitis. The purulent exudate was filled with Escherichia coli. Catheterization of the nasolacrimal duct resulted in cure. The same author experimentally produced corneal abscesses, iridocyclitis, and panophthalmitis in rabbits and guinea pigs by the injection of Escherichia coli.

Sanyal[4] (1929) reported a form of conjunctivitis caused by Escherichia coli which was not uncommon in young men laborers of Calcutta. The infection appeared to be transmitted directly from the fingers. The typical attack began as an ordinary conjunctivitis and in a day or two assumed a moderately severe character. The lids became red, swollen, and tense, the upper overhanging the lower. The bulbar conjunctiva was swollen and infiltrated and there was intense injection of the palpebral conjunctiva which had a velvety appearance. There was a copious discharge from the eyes, at first mucopurulent but later of a purulent character. There was little pain except for a dull browache. Corneal ulceration occasionally followed.

Owens[5] (1946) recently reported a case of a severe corneal abscess caused by Escherichia coli which responded to local treatment by streptomycin.

The following is the report of a case of unilateral panophthalmitis caused by Escherichia coli communior and unsuccessfully treated with penicillin and sulfadiazine.

REPORT OF CASE

History. The patient was a 48-year-old housewife who had always enjoyed good health and had never had any previous ocular complaints. Twelve days before her first visit to the out-patient department, she experienced a stabbing pain in the right eye. The following day, the eye became inflamed. Two days after the onset of the illness, she consulted a local ophthalmologist.

His report stated that the lids of the right eye were swollen and red. The globe was under tension. The anterior chamber was shallow and the pupillary area was obstructed by an opaque hemorrhagic mass. The pupil did not react to light. Vision was limited to light perception. The temperature was 99.2°F.

Two hundred thousand units of penicillin in beeswax were administered twice daily

and she also took 4 to 5 gm. of sulfadiazine by mouth each day. Urinalysis revealed a three plus reaction for sugar and injections of protamin zinc insulin were given. The eye gradually improved and she became able to distinguish form and color.

A sudden, sharp pain was again experienced in the eye eight days after the treatment was instituted and the lids became ▄▄▄▄ ▄▄▄▄▄▄ On the following day there was fluctuation of the upper lid at the orbital ridge. Following an incision made into this area, there was escape of sero-sanguinous fluid and relief of pain. On the 12th day of the infection, she was referred to the clinic and admitted to the Institute of Ophthalmology.

Examination. On admission to the hospital, the vision in the *right eye* was limited to light perception with questionably accurate projection. The lids were greatly swollen, tense, and red. The upper lid was involved more than the lower. There was a slight sero-sanguinous drainage from the incision over the upper temporal orbital margin and a small amount of purulent bloody discharge on the lid margins. The lids could not be satisfactorily opened during examination because of the intense edema and pain.

The conjunctiva was deeply congested and chemotic. The cornea was steamy and of a grayish color. About 0.5 mm. of the peripheral cornea was relatively clear. The anterior chamber appeared shallow but no details could be seen. The intraocular pressure could not be estimated.

The vision of the left eye was 20/20. The globe and adnexa were normal.

General examination was noncontributory. At this time the fasting blood sugar was 86 mg. percent. Subsequent examinations and four-part glucose, acetone, and diacetic acid urine examinations were compatible with mild diabetes.

A gynecologic examination failed to reveal any evidence of a focus of inflammation in the pelvis.

X-ray studies showed some cloudiness of the right frontal and right ethmoid sinuses and some thickening of the lining membranes of the antra. An ear, nose, and throat examination showed no definite focus of infection. The chest X-ray film was negative. The mouth was edentulous.

Frei, Brucellergin, and tuberculin (1:1,000) skin tests and the blood Klein test were negative. The complete blood count was within normal limits.

Direct smears and cultures (blood-agar medium) were taken from each eye at the time of admission.

Treatment consisted of the instillation of 2-percent atropine sulfate solution to the right eye three times a day. Penicillin ointment (1,000 Oxford units per gm.) was applied to the conjunctiva and hot compresses were used three times daily. Twenty thousand units of penicillin, intramuscularly, one gm. of sulfadiazine, and one gm. of sodium bicarbonate were given every four hours. A sulfadiazine blood level of 10 to 12 mg. percent was obtained.

Three days after admission to the hospital there was no essential change in the appearance of the lids or globe except that a small white necrotic-appearing area about two mm. in diameter was noted in the sclera and conjunctiva in the four-o'clock meridian about three mm. from the limbus. On the sixth hospital day the lens had disintegrated and the anterior chamber was very deep. Evisceration of the right eye was performed on that day.

LABORATORY STUDIES

Morphologic characteristics. A moderate number of polymorphonuclear cells and Gram-negative bacilli were present in direct smears from the right lower cul-de-sac. The lid and conjunctiva of the right eye revealed a pure culture of Gram-negative bacilli which were nonacid fast, nonspore forming, and slightly motile. With the aid of standard biologic tests, the organism was identified as Escherichia coli communior. Lid and

conjunctival cultures of the left eye showed a nonpathogenic Staphylococcus albus.

Direct smears made from the eviscerated contents revealed Gram-negative bacilli. Pure cultures of Escherichia coli communior identical to those obtained from the conjunctiva and lid margins at the time of admission to the hospital were grown from cultures taken at the time of evisceration.

Animal inoculation. An emulsified culture of the isolated bacillus was prepared and the following animal inoculations were carried out:

MOUSE. Adult white mice died within 18 to 24 hours following the intraperitoneal injection of 0.1 cc. of an 18-hour culture. Escherichia coli communior were recovered from cultures taken at autopsy of the mice.

GUINEA PIG. An intraperitoneal injection of 0.5 cc. was made, with no effect.

RABBIT. Adult white rabbits were used for intraocular studies. Injection of 0.01 cc. of an 18-hour culture of the organism into the cornea of a rabbit produced a fulminating panophthalmitis within 48 hours as did 0.05 cc. injected into the anterior chamber. The lesions in the rabbit presented changes in the globe similar to those found in the patient. When the cornea was inoculated by scarification with a needle which had been dipped into the culture or by instilla-tion of the culture into the conjunctival sac, infection did not result.

Sensitivity to antibiotics. By standard in vitro bacteriologic methods, the organism was found to be resistant to penicillin but was markedly sensitive to streptomycin.

Pathology. Fixed sections of the specimen obtained at operation showed an acute inflammatory reaction, a few Gram-negative bacilli, and early organization of a hemorrhage.

CONCLUSIONS

Although very rare, this case demonstrates the possibility of Escherichia coli communior as an etiologic agent in panophthalmitis. It also shows the importance of obtaining direct smears and cultures from the conjunctiva as an aid in determining the cause of intraocular infections. Judging from the behavior of the transference of the organism to rabbits, it seems probable that this infection was metastatic.

The organisms were not sensitive to penicillin but were found to be sensitive to streptomycin. Had the nature of the infection been determined early, and an adequate supply of streptomycin been available, the infection might have been successfully combatted.

INTRAORBITAL MENINGIOMAS

A Clinicopathologic Study*

Winchell McK. Craig,[†] M.D., and Louis J. Gogela,[‡] M.D.
Rochester, Minnesota

Until recently, intraorbital meningiomas have been almost exclusively a problem of the ophthalmologist. With the demonstration of an intracranial route of approach for their removal, intraorbital meningiomas now have come to be fully as important to the neurosurgeon as are meningiomas elsewhere.

Primary intraorbital meningiomas are comparatively rare; they have been recognized and removed surgically in 17 cases at the Mayo Clinic. Secondary, or invading intraorbital meningiomas occur more frequently.

The first report with tangible evidence of what may well have been an intraorbital meningioma was that of Scarpa[1] in 1816. He described an intraorbital growth which seemingly had its origin within the sheath of the optic nerve. This tumor was removed successfully without injury to the eye. A few years later, Wishart[2] described a similar growth in some detail.

Byers,[3] in 1901, collected from the literature of the 19th century reports of 102 intradural tumors which occurred within the orbit. Although his work was comprehensive, an accurate appraisal of the nature and the frequency of these intradural tumors was precluded by the then-existent confusion in the histopathologic identity of the various neoplasms. Most, undoubtedly, were gliomas and sarcomas.

Hudson,[4] in 1912, placed the classification of primary tumors of the optic nerve on a sounder footing in that he grouped them into three categories: gliomas, endotheliomas, and fibromas. With increasing recognition of the meningioma or endothelioma as such, reports of cases of intraorbital meningioma subsequently appeared in the literature with greater frequency. Goar,[5] in 1926, and Mayer,[6] in 1928, fixed the total number of intraorbital meningiomas described in the literature at about 40. However, whether the intradural tumors had had a primary origin within the orbit or whether they had extended into the orbit from an intracranial source had not been determined in many instances.

The origin of these tumors still is somewhat indefinite. Since the classical article on meningeal tumors by Schmidt,[7] in 1902, these growths have been thought to arise from clusters of arachnoid cells. Cushing and associate[8] pointed out that "from a histopathological standpoint, there is no apparent reason why the arachnoid layer of the optic nerve sheath should be any more exempt from tumefactions than the intracranial arachnoids."

It was the opinion of most of the earlier workers that the endotheliomas and psammomas of the orbit took their origin from the optic sheath or the sheath of Schwalbe.[9-11] The intraorbital meningioma on which Heed[12] reported was intimately attached to the pial sheath of the nerve, and it seemed that the growth sprang from this tissue.

Some of these tumors apparently arise within the optic sheath and then break through into the orbital cavity as pointed out by de Lapersonne.[13] Van Duyse,[14] in 1923, felt that his particular example was a tumor of peridural origin with secondary invasion into the optic sheath. Dandy[15] des-

cribed bilateral, collarlike endotheliomas which extended both anteriorly and posteriorly from their sites of attachment at the point of reflection of the dural sheath at the optic foramina. Cushing and Eisenhardt[8] stated that the favored point of origin of these tumors was unknown, but considered the "vicinity of the foramen" the most likely site.

Some investigators have suggested other sites of origin than the sheath of the optic nerve, or sheath of Schwalbe. Wiegmann,[16] in 1929, reported that he had removed an intraorbital meningioma. He concluded that it was "impossible" for the growth to arise from the optic sheath in view of the fact that the tumor lay outside the bellies of the muscle. Benedict,[17] in 1923, also removed a meningioma which was situated "outside the muscle cone," and Levkoeva,[18] in 1931, reported a "free-lying" intraorbital meningioma.

Levkoeva[18] concluded that the meningioma in his case had probably arisen from the "dura mater of the orbit." "However," he stated, "its development from the periosteum is not to be excluded." Others also have suggested a relationship of the orbital periosteum to meningiomas. Schreck,[19] in 1939, after studying 15 intraorbital meningiomas removed at the University of Heidelberg, concluded that these tumors arise not alone from the sheath of the optic nerve, but can occur "completely separated and free with the orbital tissues."

As was clearly pointed out by Cushing and associate,[8] meningiomas possess a tendency to expand along the lines of least resistance and force their way into "all anatomical crannies and pockets." This fact precludes critical evaluation of many of the so-called intraorbital meningiomas which have been reported in the literature. For example, the meningioma that Byers[3] reported, which had supposedly originated within the orbit, was found later at necropsy to have (very probably) extended through the intervaginal space into the orbit from its primary site along the olfactory groove. Cushing's series of 29 meningiomas of the olfactory groove included one meningioma which encroached on the intraorbital contents through the optic foramen.

Meningiomas of the sphenoidal ridge may cause unilateral exophthalmos and must be differentiated from intraorbital tumors. Elsberg and associates[20] also warned that tumors producing unilateral exophthalmos may have extended into the orbit through an enlarged superior orbital fissure or may have destroyed bone and penetrated into the orbit. However, other meningiomas, such as the suprasellar growths, which seemingly would be more likely to invade the orbit through the intervaginal space, do not do so for some "unaccountable reason."

MATERIALS AND METHODS

Several fresh specimens obtained at necropsy were examined for possible sources of tissue which might give rise to meningiomas within the orbit. The contents of the posterior two thirds of the orbit, the optic foramen, and the orbital fissures were released en masse by a transverse vertical section just behind the globe. The blocks of tissue were fixed, imbedded, sectioned, and stained by routine methods with hematoxylin and eosin. A careful study of this material then was made with particular reference to the presence, within the orbit, of cells, tissues, and other structures characteristic of the intracranial meninges. Search was made for the typical clusters of arachnoid cells and psammoma bodies.

The major portion of the study was made on cases of meningioma. The number of cases studied will be mentioned with the results. At the outset, all intraorbital meningiomas were placed into one of two sharply and mutually exclusive categories as determined by findings at the time of operation or necropsy. The tumors designated as "primary" within the orbit were those which

formed within the orbit and did not extend to occupy a position within the orbital cavity from a primary source elsewhere. The group of secondary intraorbital meningiomas was composed of meningiomas which extend into the orbit from other sources. Selection of the cases in this latter group was determined by actual invasion of an orbital opening by the tumor, by actual presence of the ex-

ANATOMIC FINDINGS

As mentioned before, the retrobulbar intraorbital contents provided by several necropsies were examined for arachnoid cells or proliferations which could conceivably act as nidi in the formation of meningiomas. In every instance, clusters of arachnoid "cap" cells and small calcified psammomas were found within the meningeal sheath
Fig. 1 (Craig and Gogela). Longitudinal section through a normal optic nerve and sheath illustrating clumping of arachnoid cells into a "cap"; (A) dura; (B) arachnoid cluster with psammomas; (C) optic nerve. The widened subdural space is an artefact (hematoxylin and eosin, ×90).

tended mass within the orbital cavity, or by the presence of a hyperostotic dorsal orbital plate and measurable exophthalmos.

In an attempt to correlate the presenting signs and symptoms of the primary tumor with its intraorbital location, special effort was made to note its relationship to the various intraorbital structures. The secondary tumors were studied specifically to determine the route of orbital invasion and findings which would be helpful in distinguishing this class of tumors from the primary group on clinical, or other grounds.

covering the optic nerve. However, similar formations were not observed along the course of other intraorbital nerves or vessels. Nor were clusters of arachnoid cells ever discovered free within the interstitial tissues peripheral to the sphenoidal fissure. The periorbita, or intraorbital periosteum, consisted of a heavy sheet of collagenous fibers and was devoid of lining cells of any sort.

Examination of a single longitudinal section through the optic nerve and its sheath often disclosed 15 to 20 fusiform clusters of 6 to 8 layers of typical, closely packed arachnoid cells. Small, deeply staining, cal-

cified psammomas were frequently observed nestling within these groups of cells (fig. 1).

CLINICAL FINDINGS

PRIMARY INTRAORBITAL MENINGIOMAS.

Primary intraorbital meningiomas have been recognized in 17 cases and treated surgically at the Mayo Clinic. The diagnosis was verified microscopically and a careful

the coverings of the optic nerve but which lay more or less freely either within or outside the muscle cone or were attached firmly to the periorbita.

The tumors were foraminal in location in three cases (fig. 2). In two of these they were bilateral. Nine growths enveloped the optic nerve or were firmly attached to its optic sheath, and the five remaining tumors appeared to arise from some source within
Fig. 2 (Craig and Gogela). (A to Q) Location and attachment of primary intraorbital meningioma in 17 cases.

study was made at the time of operation to establish that they were primary intraorbital growths. Included in this group are the meningiomas taking their origin within the confines of the optic foramen and subsequently extending both intraorbitally and intracranially.

The primary tumors were placed into 1 of 3 groups: (1) The foraminal meningiomas; (2) the growths which arise from within the sheath of the optic nerve; and (3) those which did not seem to stem from

the orbit other than the sheath of the optic nerve.

Thirteen (76 percent) of the patients were females and four (24 percent) were males. A similar sex ratio was found in the cases of the secondary meningiomas also. The ages of the patients who had primary intraorbital meningiomas extended from 14 to 55 years; and the majority of the patients were in the late middle years of life. The average age of the patients at the time of examination was 41 years. However, in-

itial symptoms and signs appeared at an average age of 35 years.

The presenting signs and symptoms consisted of visual impairment, measurable proptosis, and headache. Either visual failure or proptosis, or both, were present in every instance. Headache was recorded in only five cases and was generally described as being mild and occasional. The site of the pain was usually supraorbital or retrobulbar.

The presence or absence of proptosis or visual impairment and the time of onset of the two appeared to be related to the site of the lesion. In the three cases in which the tumors were confined to the optic foramen, progressive loss of vision was the only presenting symptom. Exophthalmometric readings failed to disclose proptosis in any of these cases. Case 1 is representative of this group.

Case reports.

Case 1. A housewife, aged 30 years, registered at the clinic on November 11, 1938. The family and personal history were irrelevant. At the age of 12 years, the patient noted that she was beginning to lose vision in the left eye. The loss of vision in that eye advanced gradually but continuously to complete blindness. The patient felt well otherwise.

About 18 months prior to registration, she noted that vision in the right eye was beginning to fail. Six months after the onset of symptoms referable to the second eye, the patient consulted a physician who performed encephalographic, spinal fluid, and serologic studies, all of which gave negative results. A diet designed to determine an allergenic basis for the optic atrophy failed to bring about a beneficial response. Since the onset of visual failure in the second eye, the patient had had a general feeling of ill health, had become nervous and had lost 10 pounds (4.5 kg.).

General physical examination at the clinic disclosed a small, slight, white woman who appeared younger than her stated age of 30 years. Objectively, physical findings were normal with the exception of those relating to the eyes. Neurologic examination gave essentially negative results except for changes in the ocular reflexes secondary to the amaurosis.

Proptosis was not present, and the eyes rotated normally. The patient was completely blind in the left eye and was able to distinguish moving objects only in the temporal field of vision of her right eye. Ophthalmoscopic examination disclosed pallor of the left disc, grade 4, on a grading basis of 1 to 4, with temporal loss of substance, grade 2. The

right optic disc similarly was extremely pallid and there was residual edema of two diopters.

Flocculation tests for syphilis and tests for possible lead or arsenic poisoning revealed nothing of significance. The blood sedimentation rate was 8 mm. in one hour (Westergren) and the concentration of protein in the cerebrospinal fluid was 30 mg. per 100 cc. Roentgenograms of the head, the optic foramina, the sinuses, and thorax showed nothing abnormal.

A diagnosis of an inflammatory or neoplastic chiasmal lesion was made and right transfrontal craniotomy was performed on December 8, 1938. On elevation of the right frontal lobe, dual, cufflike neoplasms were observed which encircled and compressed the optic nerves at the optic foramina. The tumors were dissected free and, because of some remaining vision in the right eye, the dorsum of the optic canal on that side was decompressed in the hope that there would be some restoration of function in that nerve.

The patient convalesced without incident and was dismissed from the hospital on the 13th postoperative day. Neurologic examination gave negative results at that time and findings on ophthalmoscopic examinations and examinations of the ocular fields remained unchanged. A few months after dismissal, the patient reported that she felt well and had noted some subjective improvement in vision in her right eye.

On microscopic examination the tumors proved to be meningiomas of a heavily calcified psammomatous character similar to that illustrated in Figure 3.

In this case, the tumors were slow growing and small and were situated so that any pressure they may have exerted was ineffective in producing exophthalmos.

In Case 2 the tumor originated within the sheath of the optic nerve. Visual failure and proptosis both were present.

Case 2. The patient, a nun, aged 35 years, registered at the clinic on March 21, 1947. Her chief complaint was progressively decreasing vision in the right eye during the five preceding years. The loss of vision had been almost total for a period of one year. Vision in the left eye was unaffected. Although her right eye had been feeling "heavy in the morning," she had failed to note any definite proptosis of the right eye. Except for a few sharp, right supraorbital headaches which were relieved with aspirin and rest during the preceding 18 months, the patient had felt well. The family and personal histories were noncontributory.

General physical examination revealed nothing abnormal and neurologic examination gave negative results except for depression of the light reflexes incidental to amaurosis. Vision was reduced to perception of light in the right eye and was normal in the left.

Exophthalmometric measurements disclosed prop-

tosis of 7 mm. on the right. Extraocular movements were normal. Extreme pallor and some loss of substance of the right optic disc were noted. The left eye was normal in all respects. Roentgenologic studies showed that the right optic foramen was smaller than the left and the bony collar was denser. Flocculation tests on the blood gave negative results.

The condition was diagnosed as right intraorbital tumor, possibly meningioma, and right transfrontal craniotomy was performed on April 9, 1947. The dura was stripped from the roof of the right orbit; both the dura and the roof of the orbit appeared normal. The meninges were slit along the

given a course of roentgen therapy. The exophthalmometer disclosed proptosis of only 2 mm. at that time. Vision in the right eye was nil.

On microscopic examination, the growth was found to be a meningioma of the meningotheliomatous type.

In some cases, proptosis is the chief presenting complaint. Case 3 is an example of this and of the type of intraorbital meningioma which bears no evident relationship to the sheath of the optic nerve.
Fig. 3 (Craig and Gogela). Calcified psammomas within a lobule of evenly dispersed meningioma cells (hematoxylin and eosin, ×130).

sphenoid crest, as for exploration for an intracranial meningioma, and the right optic nerve was found to be atrophic and compressed at the optic foramen by a small bit of tissue extending intracranially from within the orbit. There was no evidence of an intracranial meningioma otherwise. Consequently, the optic canal was unroofed and the orbit was decompressed; there appeared to be some osteomatous thickening of the lesser wing of the sphenoid. The sheath of the optic nerve was opened widely and a mass of tumor was recognized to the right of the nerve. With a view toward preserving the optic nerve and the muscle cone, removal was necessarily incomplete. Postoperative convalescence was uneventful and the patient was dismissed from the hospital on the ninth postoperative day.

Four months later, the patient noted a "sensation of pressure" behind the right eye and was

Case 3. A white business man, aged 54 years, registered at the clinic on October 1, 1946. Four years previously, he first noted protrusion of the right eye and fullness of the upper lid. A short time thereafter, he consulted a physician who recommended roentgenographic studies of the sinuses and the orbit. No changes suggestive of a space-occupying lesion were found at that time, nor had such changes appeared one year later. In April, 1945, the orbit was explored elsewhere through an incision in the brow and a bit of tumor was removed for microscopic study. This was reported to be a meningioma.

The patient's only complaints at the time of examination at the clinic were prominence of the right eye and fullness of the right upper lid. He had no pain, no evident limitation of ocular movements, and no subjective visual impairment.

General physical examination gave negative re-

sults except for a moderate degree of obesity and mild hypertension. The systolic blood pressure was 150 mm. Hg and the diastolic was 96. Neurologic examination disclosed no abnormalities.

The right eyeball protruded forward and laterally and there was some slight ptosis of the right upper lid. A definite mass was palpable in the superior nasal quadrant of the orbit. When specifically tested for diplopia, the patient noted doubling of vision on looking upward and to the left. Vision was recorded as being 6/6 in the left eye and as 6/15 in the right. Flocculation tests on the blood gave negative results and roentgenologic studies of the head and orbit failed to suggest the presence of a lesion.

A right transfrontal craniotomy was performed under ether anesthesia on February 3, 1947. The roof of the right orbit was removed, and it was at once evident that the intraorbital contents were under increased pressure. When the capsule was divided and the intraorbital fat retracted, a flat tumor was found along the medial wall of the orbit. Because the mass was firmly adherent to the wall, total removal was not possible. Microscopic study of frozen sections made at the time of operation disclosed the growth to be a meningioma. On examination of the fixed specimen, the tumor was classified as meningioma of the fibroblastic type.

The patient was ambulatory on the third postoperative day and was dismissed from the hospital on the 11th postoperative day. At the time of dismissal, there was still considerable edema of the soft tissues of the right eye; however, the globe was in good condition and vision in that eye had not changed.

On reëxamination seven months later, the patient felt well but exophthalmos of 8 mm. and some ptosis of the right upper lid still persisted. Vision was recorded at 6/6 in the left eye and 6/10 in the right.

Comment.

With the exception of the alteration of light reflexes incidental to the atrophic changes in the optic nerve in some cases, neurologic examination gave uniformly negative results in all but one case. In this one case, pathologic neurologic findings were ascribed to coincidental multiple lesions.

In addition to routine roentgenographic studies of the head, special poses designed to demonstrate the orbital and the optic foramina to the optimal advantage were employed. Roentgenographic findings suggestive of a lesion in the region of the orbit were recognized in 6 of the 17 cases. Bony proliferation of the roof of the orbit or

the wing of the sphenoid bone or in both sites was recognized in four cases. Two of these tumors arose from the sheath of the optic nerve and two from a source within the orbit but apparently not from the sheath.

SECONDARY INTRAORBITAL MENINGIOMAS.

The tendency of 148 meningiomas located in the region of the anterior fossa of the cranium to invade the orbit was studied. The tumors were classed into four groups according to the site of origin as reported at the time of operation (table 1). The largest

TABLE 1

TENDENCY TOWARD ORBITAL INVASION BY PRIMARY INTRACRANIAL MENINGIOMAS

Site of Origin	Total Tumors Examined	Invading Orbit	
		No.	Percent
Sphenoidal ridge	64	25	39
Olfactory groove	24		
Basofrontal region	16	5	31
Sellar region	44	5	11
Total	148	35	24

single group (64 tumors) consisted of tumors arising along the wings of the sphenoid bone. The site of origin of the remaining meningiomas was designated along the olfactory groove and in the basofrontal and the sellar regions.

The 44 sellar meningiomas include all those within and about the sella turcica. At operation, they were variously described as being "intrasellar," "suprasellar," "parasellar," or attached to the "crest of the sella."

Of the four groups, those tumors arising along the sphenoidal ridge displayed the greatest proclivity toward orbital invasion. Twenty-five (39 percent) of a total of 64 tumors presented clinical and surgical evidence of encroachment on the confines of the orbital cavity. Proptosis was present in every instance and was due to 1 of 5 various conditions: (1) Formation of an osteoma on the roof of the orbit; (2) destruction of bone and extension of the tumor through

the defect; (3) simultaneous formation of an osteoma on the roof of the orbit and extension of the tumor into the orbital cavity; (4) extension of the tumor through the orbital fissures; or (5) simultaneous extension through the optic foramen and the orbital fissures.

Sixteen (64 percent) of the 25 invading meningiomas which arose along the sphenoidal ridge compressed the contents of the orbit as a result of formation of an osteoma on the orbital roof and walls. Four tumors extended through an orbital fissure; two through defects produced by destruction of bone; two invaded the orbit through both an orbital fissure and the optic foramen, and one produced ocular symptoms by simultaneous formation of osteoma and invasion of an intraorbital tumor.

None of the meningiomas situated near the olfactory groove in this series evidenced any definite signs of orbital compression.

Of 16 basofrontal growths, five were encroaching on the orbit at time of surgical exploration. In three instances, the tumors invaded the orbital space through areas of destroyed bone. In the two remaining cases, the exact manner of extension of the growth was not determined.

Five of 44 tumors located in the region of the sella turcica were discovered to have extended to, and into, the optic foramen. In no case had extensive invasion of the orbital cavity proper occurred.

Of the 35 intracranial meningiomas secondarily invading the orbit 28 (80 percent) occurred in females. Fifteen (43 percent) of the patients were in the fifth decade of life.

All the invading sphenoidal ridge and basofrontal meningiomas produced proptosis, whereas the sellar tumors produced exophthalmos in only one case. Visual difficulties were complained of in approximately 80 percent of the cases of sphenoidal ridge and basofrontal meningiomas; whereas, in all five cases of sellar meningiomas, visual

symptoms were produced.

There was a striking paucity of other neurologic complaints which would presumably have assisted in distinguishing these tumors from primary intraorbital meningiomas. Nine patients complained of headache; three noted failing memory; two perceived decreasing olfactory sensation; and one had fainting spells.

Except for depression or absence of light and accommodation reflexes and extraocular palsies in some instances, neurologic findings were essentially absent in these groups. In no instance was there any notable disturbance of bodily functions.

Roentgenograms disclosed changes in bony or soft tissue in all but three cases. Most commonly, there was evidence of osteomatous thickening of the wings of the sphenoid in the cases in which meningiomas arose in the region of the sphenoidal ridge. The sellar tumors eroded the optic foramen or caused formation of new bone in the region of the tuberculum sellae turcicae. The basofrontal group produced an area of increased density within the orbital space or a paranasal sinus in three cases.

PATHOLOGIC FINDINGS IN PRIMARY INTRA-ORBITAL MENINGIOMAS

The primary intraorbital meningiomas were reddish, granular or nodular masses, varying in size from the small foraminal growths which measured a few millimeters in all diameters to a meningioma of the sheath which was twice the size of the eyeball. In this last case, proptosis of 17 mm. was present. Although the neoplasms often appeared encapsulated and usually presented well-defined boundaries, others had infiltrative tendencies. The extraocular muscles and the motor and sensory nerves within the orbit were engulfed by the expanding lesion in some cases (fig. 4). Total removal of such tumors results in loss of the function performed by the entrapped structures.

Four of the primary intraorbital meningiomas were of the meningotheliomatous type, 11 were psammomatous, and two were of the less common fibroblastic type. All of the foraminal growths were psammomatous. Three of the sheath tumors were meningotheliomatous and six were psammomatous. Of the five so-called extradural meningio-

the nuclei were irregular, pyknotic, and hyperchromic. These changes are probably indicative of intracellular degenerative changes.

The special Perdrau and Mallory phosphotungstic acid stains disclosed an absence of intercellular reticulin and collagen fibers. The presence of an occasional mitotic figure
Fig. 4 (Craig and Gogela). Psammomatous meningioma. Small whorls of cells are clustered into lobules imbedded among striated muscles and nerves (hematoxylin and eosin, ×75).

mas, one was meningotheliomatous, two were psammomatous, and two were fibroblastic.

In tumors of the meningotheliomatous type, the cells were arranged in a solid pattern forming a cytoplasmic blanket in which the cellular boundaries were distinguished with difficulty (fig. 5). The substance of the tumor occurred in lobules limited by minimal strips of interstitial fibrous tissue. The nuclei were generally large, round or oval, vesicular, and were rather uniformly dispersed. Higher magnification of tissue in the same case as Figure 5, however, disclosed some departure from this strictly uniform, monotonous pattern in that some of

suggested a low degree of malignant activity.

The cells composing the meningotheliomatous type of tumor resembled the arachnoidal rest cells, or "cap" cells, which occurred in clusters within the optic nerve sheath (fig. 1).

The tendency toward "whorl" formation which distinguishes the psammomatous type is shown in Figure 4. The tumor cells were grouped into small circular lobules which were further subdivided into concentric whorls of meningotheliomatous cells. It is this characteristic whorling which serves as the important distinguishing criterion in identifying the two most common types of

meningiomas. The cell type is identical in the two. However, the cells forming the peripheral layer or two of the psammomas assume an attenuated appearance.

Figure 4 further serves to illustrate the invasive tendency of the meningioma, the two psammomatous lobules being firmly imbedded among bundles of striated muscle fibers and nerve fibers.

On examination under higher magnifica-

characteristics of the two preceding types of meningiomas, the fibroblastic growths introduce certain new features. A definite, basic tendency toward whorling, distinctive of the psammomatous meningioma, may be recognized in Figure 7, which is from 1 of the 2 fibroblastic meningiomas encountered within the orbit. Numerous irregular spaces lend a suggestion of looseness to the tissue.

Examination of the detailed structure of
Fig. 5 (Craig and Gogela). Meningotheliomatous meningioma. Cells are more or less uniform and are evenly dispersed. Collagen and reticulin fibers accompany blood vessels only (hematoxylin and eosin, ×75).

tion some psammomas had been formed by the lamellar arrangement of cells about a small central capillary. More commonly, however, the cells were merely layered down on a cluster of central cells. The innermost cells often tended to degenerate and become granular (fig. 6). These bodies subsequently became hyalinized and infiltrated with calcium salts to form heavy, deeply staining, calcified masses (fig. 2).

The third histologic type of meningioma recognized in this series falls into the group designated by Bailey and Bucy[21] as "fibroblastic." While retaining some of the general

the tissue disclosed some marked departures from the more regular, compact arrangement of tumor cells seen in the preceding growths. The cells were irregular and lacking in definite boundaries and the cytoplasm appeared to trail off into light, eosinophilic, interstitial material of a homogeneous or finely fibrillar make-up. The nuclei tended to be vesicular and irregularly oval in shape. The numerous vascular spaces usually appeared well formed and were lined with endothelial cells. An occasional mitotic figure was recognized.

Special preparations of this specimen dis-

closed the presence of intercellular fibers. Silver stains brought to light delicate fibrils of reticulin interspersed among the cells and heavier strands of reticulin accompanying the larger vessels in their course. Moderate amounts of lightly staining, eosinophilic, intercellular wisps of collagenous material were demonstrable with Mallory's staining.

In this particular case, the tumor recurred and a subtotal exenteration of the

is generally considered as having introduced the less radical procedures. He made an opening through the conjunctiva and into Tenon's capsule between the rectus superior and the rectus internus. After he felt the tumor with his finger, he pried it out with a pair of scissors. Lagrange[23] modified the procedure by introducing external canthotomy.

In an effort to obtain more adequate ex-

orbit was performed nine years after initial removal.

Surgical treatment

Although Scarpa removed an orbital growth which arose from the external sheath of the optic nerve without injury to the function of the eye as early as 1816, Byers's extensive list of more than 100 intraorbital tumors of various types disclosed that, in about 70 percent of the cases, extirpation of the eyeball and the tumor was performed.

Knapp,[22] in 1874, urged conservatism in the treatment of intraorbital neoplasms, and

posure in approaching deep-lying, lateral, intraorbital tumors, Krönlein,[24] in 1888, devised an osteoplastic resection of the outer orbital wall extending down to the inferior orbital fissure. This procedure was later recognized to have definite limitations.

On anatomic examination of the orbit and its contents, McCotter and Fralick,[25] in 1943, pointed out that there are four anterior anatomic approaches to the removal of orbital tumors: (1) Resection of the temporal wall; (2) the external ethmoid approach nasally; (3) the brow incision for tumors located above the globe; and (4) the incision through the conjunctival fornix.

They concluded that only relatively small masses can be removed when these approaches are used.

Clinically, it had been recognized that the inaccessibility of intraorbital tumors and the inadequate approaches for their removal had long hampered satisfactory treatment of these growths. Although the tumors of the anterior part of the orbit could be removed readily by one of the "ophthalmic" procedures, those in a "retrobulbar" location

also that of cerebrospinal fluid leak and consequent meningitis which served to deter the ophthalmic surgeon.

The inadequacy of the various available procedures was recognized at the time of Byers's survey in 1901 when, in commenting upon the prognosis of intraorbital tumors, he stated, "The danger is not from recurrence in the strict sense of the term, but from the continued development of the intracranial portion of the tumor which it is
Fig. 7 (Craig and Gogela). Fibroblastic meningioma. A superficial tendency toward whorl formation is evident. Numerous small vascular spaces are present (hematoxylin and eosin, ×165).

had to be extirpated by touch which was an uncertain procedure.

Necessarily, many of the retrobulbar growths were removed incompletely and intracranial extensions were missed and allowed to expand within the cranium. Often, the exact nature and extent of the lesion were not recognized. Functioning eyeballs were sacrificed in an attempt at complete extirpation of tumors which could have been removed completely with preservation of sight if surgical exposure had been adequate. However, it was not only this risk of incomplete... and possible early recurrence, but

impossible to remove at the time of operation."

Accordingly, with the pioneer work of Cushing and associates and Dandy[15] in the use of the intracranial approach to the orbit, interest in the best methods of treatment of intraorbital growth received a stimulus. Simple modifications of standard surgical approaches afforded the neurosurgeon the advantages which would correct some of the ills which stopped the ophthalmic surgeon in his attack on these growths.

As Cushing and Eisenhardt so aptly put it, "The instincts and training of the neuro-

surgeon incline him at the outset to get to windward of the lesion with which he is to deal." On removal of a tumor via the intracranial route, Adson and Benedict[26] remarked that the procedure "suggests many possibilities for the transcranial approach

optic-nerve sheath by the transtemporal route.

This mode of attack first suggested itself to Dandy[15] in 1918 when he sought to correct an exophthalmos due to an osteoma in a woman, aged 28 years. He resected a bony
Fig. 8 (Craig and Gogela). Relative duration of proptosis and visual impairment in 17 cases of primary intraorbital meningioma. The case letters correspond with those in Figure 2.

to vascular and neoplastic lesions situated in the retrobulbar space of the orbit."

Dandy[27] employed the intracranial approach in removal of a combined intracranial and intraorbital growth for the first time in 1921; the particular case was one of bilateral meningioma of the optic sheaths. A short time later, Cushing and associate[8] exposed and removed a meningioma of the

growth extending around the optic foramen, and, since the roof of the orbit appeared normal, he did not consider seriously its removal because, among other reasons, "of the deformity which would result by the gravity of the unsupported brain."

The original operative case of Dandy's[15] was that of a girl, aged 13 years, who had had bilateral, progressive decrease of vision for

six years. At the time of operation, the patient was almost completely blind. Exploration disclosed firm, collarlike growths enveloping both optic nerves and extending into the foramina. The visible intracranial portion of the larger mass was resected and the operation was terminated. At a second stage operation a short time later, the posterior half of the orbital roof and the dorsum of the optic foramen were chiseled away and the tumor was traced to the globe and removed subtotally. Dandy[27] emphasized strongly the need for a simultaneous approach to the cranial and orbital cavities when such tumors were considered to be present.

The case in which Cushing and associate removed an intraorbital meningioma was that of a woman, aged 39 years, who had had progressive protrusion of the eyeball with blindness for eight years. Failing to find any evidence of intracranial tumor on lateral osteoplastic exploration, he next attacked the orbit, chipping away the orbital surface of the sphenoid. He resected and removed the optic nerve along with the tumor. Cushing and associate, in commenting on this approach, remarked that the amount of "space for maneuver" which is afforded is "greatly restricted." Hence, his operative approach must be branded as less than satisfactory.

Despite the fact that Durante,[28] as early as 1887, used the frontal intracranial approach in a case of unilateral exophthalmos probably of meningeal origin, and despite the recommendations of Dandy[27] and Cushing and associate,[8] as to the type of surgical procedure best suited to these tumors, surgeons appeared to have been influenced only a little during the years which immediately followed.

Naffziger's[29] extensive experience with transfrontal decompression of the orbit for progressive exophthalmos has further served to illustrate and confirm the satisfactory nature of the intracranial route of approach to retrobulbar tumors.

Most surgeons,[6, 16, 19, 27, 32] however, continued to employ the anterior approach into the orbit or the Krönlein osteoplastic flap. Elschnig[33] in 1927, even recommended resection of the frontal lobe of the brain through the anterior orbital approach if the new growth encroached on the brain. Thompson,[34] in 1935, in presenting an intraorbital meningioma which he removed along with the globe through a Krönlein flap, felt that this approach was indicated for "intraorbital tumors" and the "Dandy operation" was indicated for the "prechiasmal type of tumor." He apparently drew a sharp distinction between the two.

Stallard,[35] in 1935, remarked that the operation of choice for the removal of the intraorbital "endothelioma" seems to be "partial or total exenteration of the orbit," depending on the size and extent of the neoplasm.

Shortly after Adson and Benedict, in 1934, reported the removal of a hemangio-endothelioma of the orbit through a transcranial approach, Love,[36] in 1935, published an account of the same procedure for the removal of an intraorbital meningioma.

The technique employed in the transcranial approach to tumors situated within the posterior portion of the orbit is essentially similar to that used most generally by neurosurgeons in the removal of tumors involving the pituitary gland. The procedure was described in detail by Love and Benedict[37] in 1945.

The scalp is dissected free from the underlying temporal muscles through a curved incision extending upward and forward from the ear. On elevation of the bone flap, the dura is stripped from the orbital roof (or the floor of the anterior fossa). The dorsum of the orbit is then perforated and contents carefully explored. If the tumor mass should be found to expand intracranially, the meninges may be incised along their attachment

at the sphenoidal ridge and the optic foramen may be approached from the intracranial side.

General anesthesia with open drop ether over the end of a Magill intratracheal tube is generally employed.

The transcranial approach to primary intraorbital meningiomas was used in 11 of our 17 cases. The tumors were removed through a brow or anterior incision three times and through the approach afforded by the Krönlein technique once. In two cases, subtotal exenteration was considered advisable. Since its introduction, the transcranial operation was used to the exclusion of the others in all but two cases.

No deaths resulted from any of the operative procedures, nor were there any serious postoperative complications to contraindicate the intracranial operation in favor of the less extensive procedures. The results of operation measured in terms of improved visual function were dependent largely on the location of the lesion and the preoperative duration of symptoms. Little return of vision was expected and obtained in those cases in which atrophy of the optic nerve was present to any degree.

Proptosis was definitely reduced in four cases treated by the transcranial operation and in the one case in which the Krönlein procedure was employed.

The tumor recurred in two cases, in one of which the tumor was of the rapidly growing fibroblastic type.

COMMENT

In order that reports of free-lying, unattached, primary intraorbital meningiomas may not be discredited, some source for these tumors must be postulated. In some instances, the tumor mass may lie between an orbital roof which is apparently intact and the extraocular muscles. It may be suggested that these growths arise from free strands of meningeal tissue invading the orbital cavity through the orbital fissures or that the intraorbital periosteum possibly serves to give rise to these meningiomas of unexplained origin.

Another explanation is that these "extradural" meningiomas may have had an arachnoidal attachment which subsequently disappeared during the process of growth.

Within the cranial cavity, the optic nerve is first enveloped only by the pia mater, but soon gains a covering of arachnoid. On reaching the optic foramen, the nerve acquires the third or dural layer and continues with its triple meningeal sheathing as it traverses the orbital chamber to penetrate the globe.

The closely adherent periosteal and meningeal layers of the intracranial dura mater separate into the periosteum of the orbit (or the periorbita) and the outer meningeal layer of the optic sheath. This periosteum is continuous with that of adjacent bones through every orbital opening.[25, 38] At the superior orbital fissure, it continues as the external layer of the dura. The potential subdural and the subarachnoid spaces formed by the meningeal coverings of the optic nerve are continuous with the corresponding intracranial spaces.

Anatomic descriptions fail to state whether any of the coverings of the nerves to the extraocular muscles are still present after these nerves have entered the orbital cavity. The ophthalmic artery and the ophthalmic veins are apparently devoid of meningeal vestments.

Examination of serial sections of these anatomic structures in this study disclosed that meningeal tissue does not accompany these nerves and vessels into the orbit. Nor were any arachnoidal cell clusters found to lie imbedded within the normal retrobulbar intraorbital tissues. Yet, 3 of the 5 extradural tumors were of the meningotheliomatous or psammomatous type, tumors composed of a definite cell type arising only

from a similar preëxisting cell type.

Since no pathologic changes were encountered in the intracranial dura over the orbit at the time of operation, some other source must be postulated. The periorbita is composed of fibrous tissue and, therefore, cannot give rise to the meningotheliomatous or psammomatous tumors. It is suggested, therefore, that these extradural tumors may possibly have originated as arachnoid tufts which had grown into and through the dural layer of the optic sheath and had come to lie completely outside the dura.

Elsberg,[39] in 1933, and Kernohan,[40] in 1941, among others, have observed the presence of such extradural tumors in the region of the spinal cord, and the latter has offered just such an explanation for the presence of these growths in this region.

The presence of the foraminal meningiomas and of the meningiomas attached to the optic-nerve sheath may be explained adequately by the clusters or "caps" of arachnoidal cells occurring so abundantly along the intraorbital course of the optic nerve as suggested by previous investigators. In all probability, the cufflike growths arising within the optic foramen are but "sheath" meningiomas situated within a specific location. However, why this special predilection should exist and why these growths should demonstrate a tendency toward bilaterality is difficult to explain.

Microscopic examination of normal optic nerves and their sheaths did not disclose the clumping of arachnoid cells to be any more frequent or more exaggerated within the optic foramina than anywhere else along the intraorbital course of the optic nerve. Yet, 2 of the 3 foraminal tumors included in this series were bilateral, one of the growths appearing fully 16 years after its mate. Similarly, in Dandy's[15] single case of "cufflike" meningiomas the tumors were bilateral.

Reports of the occurrence of primary intraorbital meningiomas in children[6, 9, 30, 41] suggest that when these tumors occur, they do so in young persons. Hudson[17] stated that 50 percent of intraorbital meningiomas occur during the first two decades of life. Study of the 17 cases in our series, however, disclosed that the lesions appeared at much the same age as do meningiomas elsewhere within the cranium. The patients who had primary intraorbital growths came to operation at an average age of 41 years and those who had primary intracranial lesions which invaded the orbit secondarily were an average age of 43.5 years at the time of operation.

Analysis of the presenting findings (proptosis and loss of vision) failed to support the contention that the relative duration of the two diagnostic criteria may serve as a guide in differentiating these tumors from other intraorbital growths preoperatively. Investigators[32, 43] have offered precedence of exophthalmos over visual failure as a point of diagnosis in distinguishing intraorbital meningiomas from gliomas of the optic nerve. However, study of Figure 8 obliges us to conclude that such observations are unreliable criteria. Whether proptosis is to be the initial complaint, or whether the onset of visual failure will be noted first, appears to depend on the intraorbital location of the meningioma.

Although roentgen studies of the head and orbit are valuable adjuncts in the differential diagnosis of intraorbital lesions, they are probably more of negative rather than positive value in identifying primary intraorbital meningiomas. The fact that roentgenologic findings were negative in 65 percent of the primary tumors in this series is contrary to the contention that positive roentgenologic findings are suggestive of the presence of a primary intraorbital tumor. Moreover, when changes were present, they were not of a uniform nature specifically indicative of a particular lesion.

The secondary tumors, on the other hand, produced roentgenologic changes in more than 90 percent of this group. These figures

compel us to conclude that the presence of evidence of pathologic change about the orbit in the roentgenogram favors the presence of a secondary, or invading, intraorbital meningioma.

SUMMARY AND CONCLUSIONS

Seventeen cases of primary intraorbital meningioma and 35 cases of secondary intraorbital meningioma were studied in this series. The primary intraorbital meningiomas were subdivided into three groups: foraminal, sheath, and extradural.

The foraminal and the sheath meningiomas probably arose from clusters of arachnoid cells within the sheath of the optic nerve. No similar source was found to account for the extradural growths. It is suggested that they may develop from enlarging cell clusters protruding through the sheath of the optic nerve.

Intraorbital meningiomas are four times more common in women than in men and tend to occur during the middle years of life as do meningiomas located elsewhere.

The order in which proptosis and visual impairment appear does not serve as a reliable aid in distinguishing intraorbital meningiomas from other intraorbital lesions. Roentgenologic changes about the orbit are usually suggestive of an invading or secondary type of intraorbital meningioma.

The transcranial route of approach best meets any contingencies which may arise in the attack on these tumors.

TRUE PSYCHOSENSORY DILATION AND DELAYED PSYCHOSENSORY DILATION OF THE PUPIL*

A PRELIMINARY REPORT

NORMAN S. JAFFE, M.D.
Brooklyn, New York

It has long been known that the pupil will dilate in response to psychic and sensory stimuli. Fear, excitement, and rage all cause pupillodilation. Stimulation of sensory nerves similarly causes pupillodilation. The center and efferent pathway for these two different kinds of stimuli are considered identical and hence the phenomenon is known as the psychosensory reflex. This reflex has a relatively long latency period; between 0.292 and 0.46 seconds (Albrecht 0.292; Weiler, 0.36 to 0.44; Braunstein, 0.41 to 0.46).[1] The reflex consists of a quick dilation and contraction. The reaction is rapid and occurs bilaterally.

It is generally agreed that there is a cortical center for this reflex.[2] However, the efferent pathway has been the source of considerable controversy. It is more than of just theoretical importance since the reflex may be used in the practical differential diagnosis of anisocoria. The number of experiments performed in this connection has been legion, yet the conclusions drawn from them may be grouped into three main classes.

1. Dilation due to reflex inhibition of the oculomotor-nerve nucleus.

2. Dilation due to reflex peripheral sympathetic stimulation.

3. Dilation due to a combination of these two mechanisms.

Ury and Gellhorn[3] have concluded that reflex dilation occurs via inhibition of the third-nerve nucleus alone since third-nerve section abolished the reflex; whereas, it was still present after cervical sympathectomy.

They also considered that the function was purely central, since stimulation of the legs of cats with unilateral sympathectomy resulted in dilation of both pupils.

Working independently, Anderson,[4] Tschirkowski,[5] and Nishimura[6] showed that, with the cortex intact and the sympathetic intact, cutting the third nerve did not abolish psychosensory dilation. Most investigators today are of the opinion that both factors come into play and that one may be present without the other.

It is probable that this reflex does not depend on the liberation of adrenalin from the adrenal medulla since it is an extremely rapid reaction. It must, therefore, be the result of pure autonomic nervous activity.

Cannon[7] has shown quite decisively that the adrenal medulla liberates its secretion in significant amounts only under conditions of stress. Adrenalin is called forth to resist threatened dangers, to perform work, to maintain homeostasis. Thus, the sympathetic nervous system is reinforced by the medullary secretion. For maximum efficiency in coping with emergency states the body requires two mechanisms:

(1) Nervous—via immediate sympathetic stimulation; (2) hormonal—via a delayed reaction which depends on the mobilization of the hormone from the adrenal medulla.

The center for the hormonal mechanism was placed by Cannon and Rapport[8] in the upper part of the floor of the fourth ventricle. This may not be the highest center since stimulation of the hypothalamus will cause a discharge of adrenalin.

It will be shown in the following experiments that much of the confusion regarding the psychosensory pupillary reflex may be

attributed directly to the failure to recognize that there may be two phases to this reaction. The first, immediate, rapid reaction is purely nervous, due to sympathetic stimulation and probably coincidental third-nerve inhibition. The second, delayed, slow reaction is purely hormonal and depends on the liberation of adrenalin by the adrenal medulla. The second phase will only occur if the stimulus is great; that is, if an emergency state is set up. With mild stimuli only the first part of the reaction will occur.

EXPERIMENTAL STUDIES

EXPERIMENT 1

In this experiment only mild psycho-

to adrenalin. This is in accordance with Cannon's law of denervation.[9] For a more detailed explanation see a previous paper by me.[10] The present experiment was performed 2 to 3 months after the nerve sections. In no case was there any evidence of regeneration.

Each cat was placed in a cat box with the head protruding. Using Loewenstein's pupillographic technique,[11] 10 pictures per second were taken of both pupils under infrared illumination. After about three seconds, a gun was sounded. The reaction of both pupils to this psychosensory stimulus is shown in Figure 1. It is seen that the normal left pupil reacted well by dilating. The right
Fig. 1 (Jaffe). Dotted line represents the reaction of the sympathectomized right pupil. Continuous line represents the reaction of the normal left pupil. The pupils were stimulated by repeated light stimuli. Between the fourth and fifth stimuli a gun was sounded. The normal (left) pupil responded by dilating more than 4 mm. The sympathectomized (right) pupil dilated only about 1.5 mm. This demonstrates that peripheral sympathectomy largely, although not completely, abolishes psychosensory dilation.

sensory stimuli were used; for example the crack of a gun.

Postganglionic cervical sympathectomy was performed on the right side of each of eight normal cats. Horner's syndrome was apparent within 10 seconds after the nerve section. Within 10 days, in all cats, the denervated iris (right) became hypersensitive

pupil, however, showed a dilation which amounted to only one fifth the magnitude of the normal reaction.

The experiment was repeated using cats previously subjected to right preganglionic cervical sympathectomy. In all instances the results coincided with those above.

This is purely a nervous reaction and in-

volves a stimulation of the center in the cerebral cortex with subsequent peripheral sympathetic stimulation and third-nerve inhibition. In the normal eye, since the cortex, third nerve, and peripheral sympathetics are intact, the reaction is full. In the right eye we get a markedly diminished reaction because the peripheral sympathetic chain is not intact. There is no hormonal element in this reaction for, if adrenalin were liberated, the reaction in the denervated right iris would have far exceeded that in the normal iris because the effector cells of the denervated iris are hypersensitive to adrenalin (law of denervation). The small, residual reaction in the right pupil may be attributed to third-nerve inhibition.

Thus, it may be stated that mild psychosensory stimuli cause a dilation of the pupil and the integrity of this reaction is maintained by purely nervous factors—center in the cortex, peripheral sympathetic stimulation, and third-nerve inhibition; no discharge of adrenalin accompanies this reaction.

EXPERIMENT 2

In this experiment a strong emotional stimulus was used such as the excitement induced by ether anesthesia.

The eight postganglionic sympathectomized cats were used in this experiment. The cat was again placed in a cat box with the head protruding. Gauze moistened with ether was placed near the cat's nose. The animal immediately became excited. The normal left pupil dilated immediately. The right (denervated) pupil did not dilate until after 6 to 8 seconds of excitement. When it did dilate it dilated maximally and far exceeded the reaction on the normal side (figs. 2 and 3).

The same experiment was performed with the eight preganglionic sympathectomized cats. In all cases, there was an immediate dilation on the normal left side but a delayed and strong dilation on the operated right side. The reaction on the right side exceeded

that on the left side but it was slower and of smaller amplitude than that observed with the postganglionic sympathectomized cats.

It is clear that we are concerned here with both phases of the psychosensory reflex referred to previously.

The immediate reaction on the normal side was purely nervous and occurred as a re-
Fig. 2 (Jaffe). Cat with postganglionic cervical sympathectomy on the right side. Photograph shows cat under normal conditions. Note miotic right pupil (Horner's syndrome). Left pupil is normal in size.
Fig. 3 (Jaffe). Same cat as in Figure 2 during ether excitement. Note that the sympathectomized right pupil responds by dilating more than the normal left pupil. This demonstrates the "law of denervation."

sult of simultaneous peripheral sympathetic stimulation and third-nerve inhibition. The delayed reaction seen on the operated side was due to stimulation of the centers for adrenal secretion with subsequent liberation of the hormone and its action on the denervated iris.

The delayed reaction is also seen with a preganglionic sympathectomized animal but it is not so marked since sensitization of denervated structures to circulating adrenalin

is twice as great in postganglionic sympathectomized animals.

That the reaction is due to sensitization is amply demonstrated by the fact that the normal pupil returns to its original size much sooner than the denervated pupil after the ether gauze is removed.[10] Thus, with a given increased adrenalin level, the denervated structure responds more markedly than the normal structure.

EXPERIMENT 3

This experiment eliminates the hormonal factor. In two of the postganglionic sympa-

Fig. 4 (Jaffe). Same cat after right postganglionic cervical sympathectomy and bilateral adrenalectomy. The cat is shown during the excitement stage of ether anesthesia. Note that the right pupil dilates less than the normal left pupil and the right palpebral fissure is narrow. The right pupil doesn't show the "law of denervation" since the adrenal glands have been removed.

thectomized cats, bilateral adrenalectomies were performed. One week after the operation, the ether experiment was again performed. The cats became excited and the normal pupil dilated immediately. The denervated pupil, after 6 to 8 seconds, dilated only slightly (about two fifths of the usual reaction). See Figure 4.

These animals could not, therefore, respond to the ether with both phases of the "fight or flight" reaction. The immediate nervous reaction was observed since the structures subserving this reflex were intact. The delayed, marked, hormonal reaction was practically absent since no adrenalin could be produced. The small, delayed dilation

was probably due to some hepatic liberation of adrenalin.

COMMENT

These experiments show that the psychosensory pupillary reflex is a complex phenomenon consisting of two separate and distinct mechanisms. The true psychosensory reflex is a nervous reaction which has its center in the cerebral cortex. It exerts its effect by simultaneous peripheral sympathetic stimulation and third-nerve inhibition. It is an immediate reaction which has a latency period of 0.3 to 0.4 seconds. It occurs whether the stimulus is weak or strong.

The hormonal mechanism is a distinct mechanism and occurs only in response to a strong emotional or sensory stimulus. The reaction is best termed "delayed psychosensory pupillary reaction." Its center is in the floor of the fourth ventricle (perhaps in the hypothalamus). It exerts its effect by reflex stimulation of the adrenal medulla with subsequent liberation of adrenalin. The adrenalin thus formed passes to the iris by way of the blood stream and acts on the pupillodilator apparatus (fig. 5).
Fig. 5 (Jaffe). Diagrammatic representation of the pathways involved in true and delayed psychosensory dilation of the pupil. The continuous line represents the true or nervous reaction while the interrupted line represents the delayed or hormonal reaction.

Failure to recognize this delayed reaction in the past led to the erroneous interpretation of otherwise accurate observations.

As early as 1904, Anderson[4] noted that the normal pupil reacted to strong psychologic stimuli with an initial, rapid, and short dilation followed by a secondary dilation which developed and subsided more slowly and gradually. He attributed the initial reaction (the true psychosensory reflex) to stimulation of the sympathetic and the secondary dilation (delayed psychosensory reaction) to inhibition of the parasympathetic.

The latter view is untenable since reflex inhibition of the third nerve is a rapid reaction which proceeds from the cortex to the hypothalamus and then, by way of the inhibitory pathway, from the hypothalamus to the midbrain, and courses to the third-nerve nucleus which it inhibits. The distance traversed is shorter than that required for peripheral sympathetic stimulation. From the experiments herein reported it is evident that bilateral adrenalectomy would have eliminated the delayed, slow reaction. Consequently it could not have been due to third-nerve inhibition.

Ury and Gellhorn[3] more recently attributed reflex or emotional dilation of the pupil solely to inhibition of the third nerve since cutting the third nerve eliminates this. In Experiment 1, it was shown that when the cervical sympathetic chain is cut four fifths of the true psychosensory dilation is lost. Thus, the role of the sympathetic cannot be denied.

There is a further serious objection to this work. Cutting the third nerve gives a dilated pupil. Most workers believe this to be a maximally dilated pupil (problem unsettled). It cannot be expected that an emotional stimulus should further dilate such a pupil. They argue that instillation of pilocarpine contracts the pupil and still an emotional stimulus does not cause a dilation. However, it is well known that pilocarpine renders the pupil unresponsive to most stimuli (for example, reflex to light). Moreover, according to Walsh,[12] cutting the third nerve does not abolish psychosensory dilation.

Ury and Gellhorn further stated that the reaction must be a central one because stimulation of the legs of cats with unilateral cervical sympathectomy caused dilation of both pupils. However, it is probable that the dilation on the sympathectomized side was due to the delayed psychosensory reaction, since muscle contractions caused by stimulation give rise to adrenalin liberation with delayed stimulation of the sympathectomized iris. In this case, both pupils dilate but the pupil on the normal side dilates first.

Many more experiments have been performed and similar conclusions reached, but in all cases the same objections may be raised. Consequently no more instances need be cited. On the other hand, there has been much work done by others which firmly corroborates the results of the present experiments.

Byrne[13] showed that, after cervical cord transection, sciatic stimulation no longer evokes a primary reflex dilation but only a delayed form which usually occurs in 4 to 8 seconds after the onset of stimulation. The delayed dilation only occurred if the sciatic stimulation caused muscular contractions since the latter is associated with the liberation of adrenalin. If no muscle contractions occurred, no dilation occurred. Although Byrne used purely sensory stimuli his results have the same significance as those of this paper using psychosensory stimuli.

The work of Cannon[14] further shows that the reaction which depends on adrenalin liberation requires several seconds to begin. He used the denervated heart as an indicator of adrenalin liberation. Fright, rage, pain, asphyxia, and anesthesia caused, within 10 seconds, an increase in heart rate of 20 to 40 beats per minute.

SUMMARY

Much of the controversy over the psycho-sensory pupillary dilation is due to the failure to recognize that this reaction is complex and involves two separate and distinct mechanisms.

The first phase is purely nervous and involves stimulation of the cerebral cortex with subsequent peripheral sympathetic stimulation and third-nerve inhibition. It is a rapid reaction, with a latency period of 0.292 to 0.46 seconds according to three different observers. It subsides rapidly. It does not involve medullary secretion of adrenalin. It occurs with both weak and strong psy-chologic or sensory stimuli. This may be called the true psychosensory dilation.

The second phase is purely hormonal. It is a delayed reaction. It subsides gradually. It involves stimulation of the center in the floor of the fourth ventricle or in the hypothalamus with subsequent release of adrenalin by the adrenal medulla. It occurs only in response to strong psychologic or sensory stimuli. This may be termed the "delayed psychosensory dilation of the pupil."

EXPERIMENTAL STUDIES ON SYMPATHETIC OPHTHALMIA*

RAYMOND C. COLLINS, M.D.

New York

I. INTRODUCTION

This whole study is based on the allergy theory of sympathetic ophthalmia. The supporters of this theory hold that sympathetic ophthalmia is caused by an allergy to uveal pigment, melanin. De Schweinitz[1] points out that Bail and Heim gave the suggestion of the allergy theory to Kümmel and Elschnig and that Elschnig[2] went on to develop it in 1910-1911. Woods[3] has been the great champion of this theory in the United States. Despite a vast amount of work, this theory has yet to be established as fact. However, there are many observations which make the hypothesis sound most plausible. They are:

1. The time interval between the injury and the onset of the disease falls within the sensitization period as found in other immunologic experiments.

2. The histopathologic picture of sympathetic ophthalmia points strongly to an allergic basis for the disease—an allergy to pigment, as has been stressed by Friedenwald.[4]

3. The antibody reactions favor this theory. Elschnig[2] has shown that uveal pigment is capable of acting as an antigen which would cause the production of complement-fixing antibodies.

4. The skin tests with uveal pigment as described by Woods[3] suggest an allergic etiology.

5. That allergy to pigment is a factor seems indicated by the not infrequent reports in cases of sympathetic ophthalmia of bleaching of the eyelashes, leukodermic patches of the eyelids, and deafness due to involvement of the pigment cells of the inner ear.

6. Friedenwald[4] has reported an interesting case in which the sympathetic affliction had burned itself out over a period of many years and the eye was examined histologically. The choroid was replaced by scar tissue within which not a granule of uveal pigment could be found.

7. If one can evaluate therapy of this disease, it has been reported that massive salicylate therapy gives favorable results. Salicylates have been shown to reduce antibody formation in experimental animals.

8. The presence of eosinophiles in large numbers in eyes suffering from sympathetic ophthalmia points to an allergic condition.

II. RECENT ADVANCES IN THE STUDY OF AUTOALLERGY

One drawback to the acceptance of the allergy theory of sympathetic ophthalmia has been the great reluctance with which many men will accept the idea that a person can become sensitized to his own normal bodily constituents. Many years ago, Ehrlich coined the term "horror autotoxicus" to cast disparaging light on the work being carried on with regard to autosensitivity. However, advances in recent years in this field have proven Ehrlich wrong and have shown that autoallergy is not only plausible but that it does actually occur. Just to mention a few of the recent startling experimental results to sensitivity to one's own tissues we have:

1. In 1945 Cavelti and Cavelti[5] produced the clinical and pathologic picture of glomerulonephritis in rats by sensitizing them to rat kidney with the aid of Group-A beta hemolytic streptococcus.

2. Burky,[6] in 1934, produced endophthalmitis phaco-anaphylactica in rabbits by sensitizing them by the use of beef-lens toxin.

3. Another outstanding advance in the field of autoallergy came in 1946 when Kabat, Wolf, and Bezer[7] produced acute dis-

seminated encephalomyelitis in monkeys by sensitizing them to monkey brain emulsion with the aid of adjuvants.

4. There seems to be some clinical evidence today that rheumatoid arthritis is the result of an individual's sensitivity to his own connective-tissue elements.

All of these observations indicate that autoallergy is an established fact and can no longer be held as a valid argument against the allergy theory of sympathetic ophthalmia.

III. ADJUVANTS

Many of the above-mentioned advances in the study of allergic conditions have come about as a result of the use of adjuvants. An adjuvant, as used in this sense, is defined as any material or materials which, when given in conjunction with an antigen, will intensify and prolong antibody production to this antigen. They will render a weak antigenic substance strongly so. Of all the numerous methods employed to increase antibody production the technique of Le Moignie and Pinoy,[8] (1916) with mineral oil emulsified in a lanolinlike substance, with or without the addition of killed tubercle bacilli, has been found to be the most effective.

The mechanism of action of adjuvants is a complex one which is not thoroughly understood. Most workers believe that adjuvants function by setting up a reactive tissue wall about the inoculum which localizes the antigenic material at the inoculation site and, through slow continuous absorption, produces hyperimmunization. They also feel that the large monocyte response called forth by the adjuvants increases the antibody formation (Rist,[9] Casals and Freund,[10] Freund, Casals and Genghof,[11] Friedenwald[12]).

IV. PATHOLOGY OF SYMPATHETIC OPHTHALMIA

The histopathologic picture of sympathetic ophthalmia has been adequately described numerous times by competent observers. Therefore, only a brief review will be given with examples for ready comparison and evaluation of experimental results to follow. Because many eyes suffering from sympathetic ophthalmia are removed late, a mistaken belief is that the histopathologic picture should always show the iris and choroid solid with lymphocytes, epithelioid cells, and some giant cells. However, the picture which one actually sees depends on the

Fig. 2 (Collins). Section of human eye. (a) Retina. (b) Pigment epithelium with intact choriocapillaris below. (c) Nodule of infiltration in choroid, showing epithelioid cells in center of nodule.

age of the condition, and it apparently develops in stages:

1. Stage one is characterized by a focal infiltration of lymphocytes especially in the choroid and often around large veins. Figure 1 is a photomicrograph of a nodule in the

giant cells. Figure 2 shows a nodule in the choroid of an eye removed because of sympathetic ophthalmia four months after a cataract extraction. The nodule consists of lymphocytes and epithelioid cells. The choriocapillaris is spared, and the choroid be-
Fig. 3 (Collins). Section of human eye, showing tremendous thickening of choroid with lymphocytes and epithelioid cells.

choroid of an eye which was removed seven weeks after the original injury and immediately after the appearance of cells in the anterior chamber of the sympathizing eye. The nodule consists entirely of lymphocytes and there are only two such nodules in the whole choroid, as shown in the numerous sections prepared—the remainder being entirely normal.

2. Stage two is characterized by typical nodules in the choroid and iris of lymphocytes, epithelioid cells, and with or without

tween the nodules is normal. The time interval in this case is approximately the same as that during which the experimental animals were followed and is thus interesting for comparison.

3. Stage three shows the full-blown picture of the choroid uniformly infiltrated with lymphocytes and epithelioid cells and giant cells, especially the outer layers. Figure 3 illustrates this stage. This eye was removed because of sympathetic ophthalmia eight months after the original injury.

4. *Stage four* is the destructive phase in which the whole tissue is replaced by connective tissue.

No discussion of the pathology of sympa-

Fig. 4 (Collins). Dalén-Fuchs nodule in human eye.

thetic ophthalmia would be complete without mentioning the Dalén-Fuchs nodules. These are localized nodules of the pigment epithelium of the retina which were first described by Dalén[13] in 1904 and then by Fuchs[14] in 1905. They are formed by a localized proliferation of the pigment epithelium which has undergone autolysis and has been invaded by macrophages and epithelioid cells.

The Dalén-Fuchs nodules are considered by some to be pathognomonic of sympathetic ophthalmia. Others claim that they are found in inflammatory conditions, particularly tuberculosis. However, Friedenwald[4] stresses that the alterations of the pigment epithelium seen in other conditions never show the evidence of autolysis and phagocy-

tosis by epithelioid cells of the pigment granules as seen in sympathetic ophthalmia. Figure 4 shows a typical Dalén-Fuchs nodule from a human case of sympathetic ophthalmia.

V. EXPERIMENTAL WORK

1. *The goal* of this study was to produce in experimental animals a condition that simulated what is known as sympathetic ophthalmia in humans. This must be accomplished before the allergy theory can be established as fact.

2. *Choice of animal.* For this work we have chosen to use the guinea pig, because Zinsser[17] some years ago pointed out the similarity of the immune and anaphylactic reactions in guinea pigs and human beings. We learned from experience that white pigs with pigmented eyes or predominantly white pigs gave the best results in our work.

3. *Antigen.* In this work, macerated whole uvea was used as the antigen. It is true that the pigment of this tissue is believed to be the antigenic factor. Nonetheless, with our present meager knowledge regarding the chemistry and properties of melanin, it was felt that it would be impossible to obtain the pure product in its natural state.

Chemists working with this substance disagree about its solubility and properties. Despite the work of Elschnig,[2] von Szily,[15] and Woods,[3] who report on the use of pure pigment, it was felt that this was still impossible.

Mason,[16] after a review of the many works on the chemistry of melanin, states, "One is led to the conclusion that only the most gentle methods of separation of the pigment from its naturally occurring concomitants can be expected to yield an unchanged product. The weight of evidence indicates that, in the majority of cases in which isolation of melanin has been reported, the compositions found represent those of altered natural pigment. Since the recent study of Herrmann and Boss it has become evident

that the melanin granule is a highly complex aggregate not only of pigment, but also of at least three enzyme systems in a protein matrix. Should the pigment, which is apparently quinonoid, initially be bound to the granule by few or no primary valence bonds, it is likely on chemical grounds that destruction of the organization of the granule would result in rapid conjugation."

The pigment granule is intracellular, and it was felt that, with a limitless number of washings, one could never obtain pure pigment by mechanical means. Once chemical methods have been applied there is no way of knowing how the antigenicity of the melanin has been altered.

4. Procedures and results. In work on immunity it is known that young, healthy animals produce the highest titer of antibodies. Thus we used in all cases young, healthy guinea pigs.

SERIES ONE

Heterologous uveal tissue antigen. It is believed by many that uveal pigment is organ specific and not species specific, or only weakly so. Thus, in this series an attempt was made to sensitize guinea pigs to beef uvea (heterologous). Two animals were given intraperitoneal injections and four were given intramuscular injections of a mixture containing macerated whole beef uvea and adjuvants, which will be described later.

Three months after the last injection of this material the animals were killed and the eyes examined histologically. Of the six animals followed, one was positive (two eyes) and five were negative.

By positive is meant that the sections of the eyes showed good-sized areas of focal infiltration of lymphocytes and epithelioid cells in the choroid:

Figure 5 shows a nodule consisting of lymphocytes and epithelioid cells in the choroid of the left eye of the positive animal. Figure 6 shows a similar nodule in the

right eye of the same animal. The choroids of both eyes were filled with numerous such nodules. Bruch's membrane was intact and the retina was normal throughout.
Fig. 5 (Collins). Section of left eye of guinea pig No. 292. (a) Retina. (b) Nodule of lymphocytic and epithelioid-cell infiltration in choroid. (c) Sclera.

SERIES TWO

Homologous uveal tissue antigen. In this series, an attempt was made to produce the picture of sympathetic ophthalmia in guinea pigs using guinea pig uvea as the antigen (homologous). The procedure was as follows:

A saline suspension of macerated guinea pig uveas was mixed with mineral oil, aquaphor, and heat-killed tubercle bacilli. Each
Fig. 6 (Collins). Section of right eye of guinea pig No. 292. (a) Retina. (b) Nodule of lymphocytic and epithelioid-cell infiltration in choroid. (c) Sclera.
Fig. 7 (Collins). Biopsy of inoculation site.

injection was composed of 0.2 cc. paraffin oil, 0.1 cc. of aquaphor, heat-killed tubercle bacilli (0.5 mg. in the first, 0.85 mg. in the second, and 0.5 mg. in the third batch of antigen mixture), and 1.6 uveas per injection in the first mixture, 3.35 uveas in the second, and 0.7 uveas in the third.

This material was injected intramuscularly or intraperitoneally into 25 young, healthy guinea pigs. Each animal received 0.5 cc. of the above mixture in a leg muscle at weekly intervals for three doses. A fourth such injection was given at the end of five weeks. In a few, the fourth intramuscular injection was replaced by an intraperitoneal injection of the same amount. The animals were followed for from 3 to 6 months after their first injection.

Immediately before killing 12 of the animals, a sterile sample of blood was drawn

from the heart. Complement fixation tests run on these 12 sera showed no complement-fixing antibodies to guinea-pig uvea.

Because there is a virus theory of sympathetic ophthalmia, eight of these blood samples were studied for the presence of a virus. No virus was isolated by the routine methods of checking for these organisms. Likewise, because there is a bacterial theory of this condition, eight of the samples were cultured for the presence of bacteria and all of the specimens of blood were found to be sterile. An electrophoretic pattern was run on one serum and no increase of gamma globulin was demonstrated.

At the end of the chosen interval, that is, from 3 to 6 months, the 25 animals were weighed and killed. All 25 had gained much weight and appeared healthy. The eyes were removed immediately after death and fixed in Zenker's fixative and serial sections were made of all the eyes. Biopsies were taken of lung, liver, spleen, kidney, and inocula-iton site in all of the animals.

Figure 7 shows a biopsy of an inoculation site of one of the animals. It shows the

by these cells. As pointed out above, one theory of action of adjuvants is that they call forth a large response of mononuclear cells which, in turn, increase antibody production.

Figure 8 shows a biopsy of the liver of one of the animals. It shows how the re-

Figure 9 shows the nodules in the choroid of the left eye of guinea pig No. 253, and Figure 10 shows the same findings in the right eye of this same animal.

Figure 11 shows one of these choroidal nodules of experimental animal No. 253 under higher power. Bruch's membrane is in-
Fig. 14 (Collins). Low-power magnification of a section of right eye of guinea pig No. 133. (a) Nodules of lymphocytic and epithelioid-cell infiltration in the choroid. (b) Dalén-Fuchs nodule.

ticulo-endothelial system of the liver, the Kupffer cells, have phagocytosed the pigment. Biopsies of the lung and spleen also showed marked phagocytosis of pigment by this system. The reticulo-endothelial system is important in the formation of antibodies.

Of the 25 guinea pigs so treated, 12 (24 eyes) were positive, that is, showed large areas of focal infiltration of lymphocytes and epithelioid cells in the uvea and changes in the pigment epithelium resembling Dalén-Fuchs nodules. It is to be emphasized that the eyes of these experimental animals were never touched or traumatized in any fashion until they were removed for sectioning after the death of the animal.

tact and there has been a proliferation of the pigment epithelium of the retina and some loss of retinal substance over this nodule probably as a result of an autolytic process taking place in the nodule. Careful examination of these sections shows that there is no true invasion of the retina.

Figure 12 shows the nodules in the choroid of the left eye of another positive animal, No. 133, and Figure 13 shows a high power magnification of one of these nodules. The nodule is composed of lymphocytes and epithelioid cells, Bruch's membrane is intact, and the choriocapillaris is spared.

Since sympathetic ophthalmia is a bilateral condition, Figure 14 shows the nodules in

the choroid of the right eye of this same animal, No. 133.

Figure 15 shows a Dalén-Fuchs nodule from the right eye of animal No. 133. Here again one sees a proliferation of the pigment epithelium, epithelioid cells, and an evidence of an autolytic process as shown by a loss of the retinal substance over the nodule. Many of the eyes of the positive animals showed these nodules.

SERIES THREE

Controls. Nineteen guinea pigs were run as controls. Fourteen of these animals received four intramuscular injections at the same time intervals as was used in the treated animals, that is, 1, 2, 3, and 5 weeks.

Each injection, consisting of 0.5 cc., contained the same amount of adjuvant—aquaphor, mineral oil, and heat-killed tubercle bacilli (0.5 mg. per injection)—as was used in the test animals above.

In addition, each injection contained an amount of albino guinea-pig liver tissue equivalent in dry weight to the approximate dry weight of guinea pig uvea in each experimental animal injection. Albino guinea-pig liver was chosen as a neutral, noneye tissue which we could be certain contained no melanin.

Five of the 19 guinea pigs received the same series of intramuscular injections of adjuvant alone. Each injection contained the same amount of adjuvant—mineral oil, aquaphor, and heat-killed tubercle bacilli—as was used in the treated cases.

All of the control animals were followed for from 3½ to 5 months. At the end of the chosen time interval, the animals were killed and biopsies of the lung, liver, spleen, kidney, and site of injection were taken. The eyes were removed immediately after death and fixed in Zenker's fixative and serial sections were made of all the eyes.

Microscopic examination of every section showed all of the 19 control guinea pigs (38 eyes) to be negative, that is, there were no abnormal histologic findings in any of the eyes.

SUMMARY

1. Observations favoring the allergy theory of sympathetic ophthalmia were presented.

Fig. 15 (Collins). High-power magnification of Dalén-Fuchs nodule in right eye of guinea pig No. 133.

2. The histopathologic picture of sympathetic ophthalmia was briefly reviewed.

3. Experimental work showing an attempt to sensitize guinea pigs to uveal tissue with the aid of adjuvants, mineral oil, aquaphor, and heat-killed tubercle bacilli was presented. One (two eyes) of six guinea pigs, using heterologous uveal tissue, beef uveas, plus the above adjuvants, showed focal areas of lymphocytes and epithelioid-cell infiltration in the choroid of both eyes.

Twelve (24 eyes) of 25 guinea pigs using homologous uveal tissue, guinea pig uveas, plus adjuvants showed similar lesions. Many showed Dalén-Fuchs nodules.

Nineteen control guinea pigs given adju-

vants plus albino-liver tissue, or adjuvants alone, showed no abnormal findings in the eyes.

DISCUSSION

DR. JONAS S. FRIEDENWALD (Baltimore): I think Dr. Collins' report is very impressive. I would like to have more detailed histologic pictures before I can make up my own mind as to whether the picture produced, and to what extent the picture produced, resembles that of sympathetic ophthalmia.

I should like to make one point in regard to whether or not melanin itself is the necessary antigen in an allergic theory of sympathetic ophthalmia. A number of years ago Dr. Robert Hare and I were studying the skin reactions of patients with sympathetic ophthalmia to various inocula, and comparing the reactions to those produced in the skin of these same patients by uveal pigment preparations.

We found that we could make an emulsion from the choroid of albino rabbits which, when injected intradermally into sensitive patients, elicited an epithelioid-cell and round-cell reaction quite analogous to that produced in the same patient by an emulsion of choroid from a pigmented rabbit, and consequently we concluded that the melanin itself was not the antigen, but perhaps the melanin granule contained a matrix which was the antigen.

DR. ROBERT DAY (Baltimore): Were there any changes in the anterior uvea or any clinical signs?

DR. DAVID G. COGAN (Boston): I would like to ask the essayist if he investigated other pigment-bearing structures; for example, in the choroidal plexus, and if there was any lymphocytic reaction anywhere else in the body. From the pictures, I would judge not.

DR. RAYMOND C. COLLINS (New York): The question as to whether or not there were any changes in the anterior uvea: The iris was entirely free. Many of them showed mild infiltration of lymphocytes in the ciliary body.

As to whether there was a lymphocytic reaction elsewhere in the body, biopsies taken as outlined, of the lung, liver, spleen and kidney, showed no lymphocytic infiltration, merely this phagocytosis of pigment that you saw on the slides.

DR. COGAN: Lymphocytic reaction in other pigmented-bearing structures? Did you investigate any other pigment-bearing areas?

DR. COLLINS: No, we did not.

DR. COGAN: That would be an interesting thing to do.

DETACHMENT OF THE ANTERIOR LAYERS OF THE IRIS (IRIDOSCHISIS)*

REPORT OF A CASE‡

JAY G. LINN,† M.D., AND JAY G. LINN, JR., M.D.

Pittsburgh, Pennsylvania

A separation or detachment of the anterior layers of the iris is a very rare condition, first described by Schmitt[1] in 1922 and named iridoschisis (iris splitting) by Loewenstein and Foster[2] in 1945. It is an acquired condition of a degenerative nature and is characterized by a separation of the iris into two distinct layers. The anterior layer appears as a thin transparent stratum of iris tissue attached to the posterior layer centrally in the region of the sphincter and peripherally near the iris root. The main body of this layer is composed of radial fibers which, in places, undergo fragmentation. The loose ends float singly or brush-like in the aqueous. The posterior deeply pigmented layer of the iris is easily seen through this anterior layer even where no fragmentation has occurred.

Ten cases have previously been reported in the literature to which we are adding an eleventh. They are as shown in Table 1.

CASE REPORT

Clinical history. B. C. L., a 58-year-old white man, was first seen by one of us (J. G. L.) in May of 1938, at which time he complained of blurred vision of the right eye. The corrected vision at that time was: R.E., 20/100; L.E., 20/200. He had always had poor vision in the left eye and an opera- tion was performed in 1912 to correct a left esotropia.

A diagnosis of chronic simple glaucoma of the right eye was made on the initial examination and a corneoscleral trephining operation was performed a few weeks later. Good filtration was obtained and the post- operative corrected vision was 20/50+3. The tension has remained normal or sub- normal since the operation.

In October, 1946, a reduction of the vision of the right eye caused by a nuclear cataract was noted. Ophthalmoscopy at this time revealed a pallor of the disc and pig- ment deposits in the retina.

In February, 1948, an atrophy of the iris with detachment of the anterior layers was first noted. The lenticular opacity had progressed and the fundus could not be seen.

Past medical history. Our patient had an appendectomy performed in 1928 which was followed in four weeks by a right nephrec- tomy for a kidney stone. Postoperative cul- ture from the kidney was positive for Myco- bacterium tuberculosis. He has enjoyed good health since that time.

Present ocular findings. In October, 1948, visual acuity of the right eye was 4/200 and of the left eye, 20/200. The right eye was divergent about 10 degrees. Both pupils re- acted normally to light.

Slitlamp examination. Right eye. There was beginning endothelial dystrophy of the cornea (cornea guttata). No keratic pre- cipitates were present and the aqueous was clear.

The iris had a surgical coloboma at the 12-o'clock position from the corneoscleral trephination. The entire iris was atrophic. This atrophy was more advanced in the ciliary zone. In this area, between the

Linn and Linn	58 M.	Chronic simple glaucoma, nuclear cataract	Tuberculosis of kidney with stone formation

sphincter muscle and the base of the iris, there was a separation into two layers. This was more evident in the nasal half of the iris. The main body of the anterior layer consisted of radial fibers. Some of these fibers contained granules of uveal pigment. In the area between the 3- and the 6-o'clock positions there had been a rupture of these radial fibers. The free ends were floating in a brushlike manner in the aqueous. A depigmentation of the anterior layer had resulted in a translucency which enabled the slitbeam to pass through so that the deeply pigmented posterior layer could be easily observed. This translucency was reduced in the region of the sphincter which apparently was uninvolved because the pupil reacted promptly to light. Examination of the lens revealed a diffuse nuclear opacity.

Left eye. The cornea had a nebulous opacity involving the stroma of that portion just below the pupil. An endothelial dystrophy in the same stage as that of the

right eye was present.

There was beginning atrophy of the iris with some absorption of pigment of the anterior layers. Only in some areas had this depigmentation progressed so that the posterior layers could be seen through the anterior. No separation of the layers was evident. No cataract formation was evident in the lens.

Gonioscopy. Examination of the angle of the anterior chamber with the Allen prism revealed complete occlusion of the angle of the right eye by peripheral anterior synechia.

The angle of the left eye was open only in a small area of the nasal portion. No pigment could be seen in this area.

COMMENT

Histologic studies of the iris have been reported by Loewenstein, Foster, and Sledge[2, 9] which confirm the biomicroscopic findings. They found general atrophy of the iris
Fig. 1 (Linn and Linn). Appearance of the detachment of the anterior layers of the iris in the case herein reported.

tissue. The anterior layer consisted in some places of "thin floating membranes" and in others of "fragile grayish tissue like the finest lace." The free floating radial fibers were found to contain a blood vessel with a thickened endothelium. The blood vessel was filled with erythrocytes. The sphincter muscle was normal and the dilator fibers were hypertrophied. In their second case there was some evidence of phagocytosis of pigment.

An analysis of the reported cases reveals no specific cause for this peculiar form of iris atrophy. Senility, glaucoma, trauma, iritis, and diabetes have been suggested by individual authors. Apparently, any of these may be a factor which acts on the more delicate spongy tissue of the iris. The atrophy of the more dense and better differentiated tissues of the iris may follow at a later stage.

In no case has any synechia of the freely floating fibers to the cornea been recorded. No hyphema has resulted from rupture of these fibers.

Dollfus[8] performed an iridectomy on his patient which he followed in one month with a lens extraction. There was no complication of either procedure. We plan to extract the lens of our patient at a later date.

Our case is significant only in that the ruptured radial fibers of the anterior iris layer are possibly more prominent and the artist has been able to demonstrate them (fig. 1) better than in the previously reported cases.

SUMMARY

A case of detachment of the anterior layers of the iris (iridoschisis) is reported. The previously reported cases are listed. No specific cause can be assigned to this unusual degenerative condition.

CORRELATION OF MICROSCOPIC AND SLITLAMP EXAMINATIONS OF DEVELOPING HEREDITARY CATARACTS IN MICE*

GEORGE K. SMELSER, PH.D., AND LUDWIG VON SALLMANN, M.D.

New York

A strain of Swiss albino mice which invariably develops hereditary cataract at an early age was placed at our disposal by Professor Landauer of the University of Connecticut. This stock appeared to be of normal, vigorous animals with the exception of the lens pathology to be discussed, and a deformity of all four feet which is inherited as a recessive character, called brachypody by Landauer. There is no reason to believe that this latter condition has any relation to the cataract formation.

It was planned to follow the progress of developing cataracts in these mice both by clinical study with the slitlamp and histologic examination, and to attempt correlation of the data obtained by the two methods. In addition, some preliminary studies were made which might suggest other approaches to the problem of the mechanism of the cataractous process. For these purposes a colony of animals was established, maintained on our stock diet supplemented with one based on growing chick mash with added vegetable and cod-liver oil and brewers' yeast. A control group of mice, also of the Swiss albino strain, but which is regularly free of the lenticular abnormalities, was maintained under the same conditions to provide normal material for comparison.

One hundred and five mice were examined, 70 of them on several occasions with the slitlamp and corneal microscope by one of us (L. v S.). Twenty-five of these were killed at various stages for microscopic study. The lenses of eight normal mice of various ages were also studied microscopically. Most of the sections were prepared by the celloidin method, 8 and 10 microns in thickness, and stained by standard procedures. Frozen preparations were made of 14 eyes and the sections examined for fat, cholesterol (Schultz reaction), and birefringent material.

OBSERVATIONS

The lenses appeared to be normal during the first 35 to 40 days of life. Occasionally fine remnants of the hyaloid vascular system were seen at the posterior surface of the lens but not in greater frequency or size than in normal mice of the same age. In two mice, both 39 days old, an irregularity of the specular reflex and a fine stippling were noted at the posterior pole with slitlamp examination. This appearance may be normal.

One of these lenses appeared to be quite normal when studied histologically, but the other three showed some deviation from the appearance of normal control lenses. This was evidenced by (1) the presence of small basophilic patches in the cortex near the posterior pole, (2) slight disorganization of the lens fibers at the posterior pole of the lens nucleus, (3) lack of preciseness in the posterior boundary of the nucleus (fig. 2).

It will be noted (fig. 2) that the lens abnormality involves the posterior border of the lens nucleus, very deeply stained, and all of the posterior cortex at this point. The posterior cortex (neutrophilic in staining reaction) appears to be slightly narrower than normal so that the nucleus lies nearer to the posterior pole than normally.

By 55 days of age cataracts were generally quite definite. The typical appearance seen clinically in this age group began with a circle of tiny gray dots around the posterior pole in the cortex of the lens, which was the earliest stage indentifiable as abnormal. A section of this lens is shown in Figure 3. The
Figs. 1 to 5 (Smelser and von Sallmann). 1. Section of normal mouse lens.

2. Section of lens showing definite deformation at the posterior pole. Slight stippling, regarded as probably normal, was seen in this region with the slitlamp. Note the presence of some remnants of the hyaloid vascular pattern. Age of mouse 39 days.

3. Section through posterior pole of a lens which showed the earliest stage identifiable as abnormal by slitlamp examination. Note the very narrow cortical zone and the disruption of the more central fibers. Age of mouse 55 days.

4. Clinical appearance of an early stage in the cataract development. The opacity lies at the posterior pole of the lens. Age of mouse 66 days.

5. A slightly more advanced stage in the cataract formation. Age of mouse 66 days.

fibers of the posterior portion of the nucleus appear to be swollen and separated.

In addition, marked, though small, opacities were found clinically in the posterior polar region of other animals of this age group. They ranged from triradiate localized opaque masses to irregularly shaped opacities sometimes containing minute vacuoles. The clinical appearances of two such types are shown in Figures 4 and 5.

The histologic appearance of such an opacity, although represented by an older case, is shown in Figure 6. These opacities increase in size and density and often extend into the adjoining layers as a gray veil with fine striations. This veil could not be identified in histologic preparations.

In the further development of the cataract, irregular opacities appeared in the perinuclear area, as seen with the slitlamp, and, in some cases, minute vacuoles which seemed to lie in the subcapsular zone. Microscopic study of these lenses revealed a pyramidal homogeneous mass at the posterior pole very like that seen in earlier stages (fig. 6). The basophilic lens nucleus appeared to be displaced posteriorly and surrounded by cortex with a neutrophilic staining reaction. Around this zone was a markedly crescentic basophilic area, wide anteriorly and tapering rapidly toward the posterior pole.

On the anterior surface of this crescent were a row of small vacuoles (fig. 7). The lens cortex appeared to be normal. When the opacity involved the perinuclear zone it often formed a rather homogeneous layer around the nucleus which appeared clear. In other instances, a second more peripheral opaque zone became visible, separated by a clear interval from the more central layer. The histologic appearance of the anterior portion of such a lens is shown in Figure 7.

Finally, in a third group of animals the nucleus became cataractous before the layers of peripheral opacity developed. Sometimes a thin, dense sheath surrounded the nuclear opacity as shown in Figure 9. The further

progress of the cataract was apparently not influenced by the character of the intermediate state.

Vacuoles occurred frequently, but only in animals three months of age or older. In most cases these vacuoles appeared to be empty, but in a few they contained a stainable coagulum. Such a vacuole is shown in Figure 8. This vacuole was not noted in the slitlamp examination, but small subcapsular vacuoles were. These, on the other hand, were not found microscopically.

A water cleft was also noted in this eye in the slitlamp examination, and a cleft occurred at the anterior pole of the basophilic perinuclear zone. This cleft contained a homogenous material which stains very like the perinuclear material, although no structure is apparent. Many of the larger vacuoles, seen with the slitlamp, were arranged equatorially, as shown in Figure 9, although in some they appeared to fill the entire anterior part of the lens (fig. 10).

In practically all cases the lens was found to have ruptured at the posterior pole and the nucleus extruded into the vitreous. This occurred first at 70 to 80 days of age, although all animals were not so affected at this time. In older mice this phenomenon was almost invariable.

The extrusion of the lens nucleus was not obvious in the slitlamp examination, possibly because more anteriorly placed opacities obscured the view. The extrusion of the lens is not a technical artefact occurring during the histologic procedures, for it could be demonstrated by dissection of the globe prior to fixation. Such a lens is shown in Figure 11. Cataractous but intact lenses dissected out of the eye and placed in fixatives did not rupture.

Figure 8 shows what may be a very early stage in lens extrusion. The capsule is broken at the posterior pole and the lens nucleus appears to be slightly protruding. The typical appearance of these later stages is shown in Figure 12. The capsule has ruptured, and its
Figs. 6 to 8 (Smelser and von Sallmann). 6. Section through the posterior part of a cataractous lens showing the histologic appearance of an opacity similar to those shown in Figures 4 and 5, although it is from an older mouse, aged 125 days.

7. Anterior portion of a cataractous lens showing a row of small vacuoles lying deep in the cortex on the surface of a basophilic crescent-shaped band of material anterior to, and separated from, the lens nucleus. Age of mouse 125 days.

8. Section of a cataractous mouse lens, age of mouse 146 days, showing a coagulum filled vacuole in the anterior cortex, not noted in slitlamp examination. The nucleus appears to have been displaced posteriorly. The posterior lens capsule may have ruptured. This appears to be a very early stage of nuclear extrusion.

broken ends coil like a watch spring on either side of the opening. A dense basophilic mass, the remnant of the crescent of perinuclear material shown in Figure 7 was retained within the capsule and probably interpreted clinically as opaque nucleus.

After it was known that the lens frequently ruptured, evidence of that fact could be obtained on slitlamp examination by noting a flattening in the anterior surface of the lens and an increase in the depth of the anterior chamber.
Figs. 9 to 12 (Smelser and von Sallmann). 9. Clinical appearance of a more advanced cataract showing many equatorial vacuoles. Age of mouse 95 days.

10. An extreme case of vacuolation of the cataract. Age of mouse 219 days.

11. Drawing of a ruptured lens dissected from the eye showing the extruded nucleus. Vacuoles can be seen in the equatorial region. Age of mouse 146 days.

12. Section of a lens after rupture of the capsule and extrusion of the lens. The retained deeply staining material was opaque and obscured the extruded nucleus in the slitlamp examination. The vacuoles are similar to those shown in Figures 9 and 11. Age of mouse 125 days.

Due to the relatively small volume of vitreous and large lens in mice eyes, the extruded lens nucleus and lenticular material often came into contact with the retina. Various degrees of retinal reactions were observed. Aggregations of small cells with deeply staining nuclei, possibly lymphocytes, were frequently found. The ganglion cells were sometimes misshapen or unrecognizable. In one case, elongated spindle-shaped cells,

similar to fibroblasts were found. Of the 12 eyes examined all but three showed some retinal abnormalities. In the three which did not, the lens material was not in direct contact with the retina. These may have been cases in which the lens was very recently ruptured.

lenses in which no crystals had been noted. In one case there was an agreement, in that neither cholesterol nor crystals were found.

The histochemical test for cholesterol and the slitlamp examination report on the crystals were in agreement in 50 percent of the cases. It should not be concluded from this

TABLE 1

CORRELATION OF IRIDESCENT CRYSTALS WITH THE HISTOLOGIC DEMONSTRATION OF FAT AND CHOLESTEROL IN THE LENS

62 O.S.	12	++	+	+
62 O.D.	12	++	+	++
4 O.S.	old	++	−	−
4 O.D.	old	+	−	−

Fat stains (Oil red 0) applied to sections of the 14 eyes fixed in 3-percent formalin revealed considerable fat in droplets of variable size. These fat droplets would appear as vacuoles in the celloidin preparation, but it is certain that most, if not all, of the larger vacuoles, such as shown in Figure 12, did not contain fat.

In many instances cataracts of mice eight months or older were seen with the slitlamp to contain iridescent crystals which are usually considered to be cholesterol. These crystals had been noted in eight of the 14 eyes at the time of autopsy. No crystals were noted in the other six eyes. A histochemical test (Schultz reaction) for cholesterol was carried out on all sections and the results are given in Table 1.

Cholesterol was identified in six of the eight lenses in which the crystals were seen, however, cholesterol was also found in five

that the crystals do not necessarily represent cholesterol, for they may occasionally have been obscured in the slitlamp examination by overlying opaque masses.

In those cases where they have been found in vivo and no cholesterol was identified histologically, the crystals may have been so fine and dispersed that they were not visible in the sections. However, in these cases all of the sections cut from the eye were subjected to the Schultz reaction in order to discover isolated minute deposits of cholesterol, which was usually associated with fat and located in microscopically visible droplets.

It may be noted that cholesterol and fat were always found in the same lenses and as early as four and one-half months, whereas the iridescent crystals were not observed in animals younger than 8½ to 9 months of age.

The rupture of the lens capsule in this

type of cataract suggested that the thickness of the capsule should be investigated in lenses prior to its break at the posterior pole. Accordingly anterior and posterior capsule thicknesses were determined in a series of lenses of normal and cataractous mice. The measurements, made with an ocular micrometer, of the anterior capsule are much more precise than those of the posterior capsule. Each value given in Table 2 is the average of measurements of several sections and shows

gested to us that the lens epithelium might also show abnormalities. Qualitative examination of the epithelium of early cataractous, unruptured lenses revealed no obvious peculiarities. The central portion of the lens epithelium occasionally stained poorly and the nuclei seemed to be rather far apart. Accordingly nuclear counts were made in representative sections of a number of lenses from normal and cataractous mice. These sections were then projected at ×100 magni-

Mice No. 101 and No. 103 appear clinically normal or very nearly normal.

that the lens capsules of mice of the cataractous strain are thinner than normal before a change in the lens can be seen with the slit-lamp.

This difference in the anterior capsules continues when the opacity of the lens becomes marked, but the posterior capsule becomes even thinner, in most cases, until it breaks. Of course, if the lens is swelling prior to its rupture, the capsule may be passively thinned by stretching. However, this process presumably is not very far advanced in mice whose lenses are still clinically normal at 39 days of age.

The thinning of the lens capsules sug-

fication and the length of the epithelium measured in millimeters.

All of these sections were 10 microns in thickness. The number of nuclei counted was divided by the length of the section of epithelium in which they were located to give the relative density of the cellular population in a known area of lens epithelium. These data, (table 3), although somewhat variable, show that there were about 25 percent fewer cells in a unit area of the lens epithelium in the cataractous mice. The data are not sufficient to determine whether a deficiency in epithelial cells existed in the very earliest stages and, therefore, it cannot

be concluded that the sparseness of the epithelial population is a primary or a secondary phenomenon resulting from stretching of the epithelium, if indeed this does occur.

Whatever the nature of the earliest changes in this or other cataract development may be, there is general agreement that the proportion of soluble proteins in the lens decreases. It was thought that, by electrophoretic analysis of the soluble lens proteins of early and late cataracts, a suggestion could be had indicating which of the

minations[†] were made on aliquots of the solutions submitted for electrophoretic analysis. These experiments were carried out twice—a total of six analyses of pooled groups of lenses. The mice in Groups A and B were of the same age.

Three electrophoretic patterns are shown in Figure 13. The size of the pattern is proportional to the concentration of the protein solution submitted and is, therefore, of no significance here. The area occupied by each of the several components is also proportional to the concentration of that component,

* Number of nuclei = the number counted in 3 to 4 sections. Length of epithelium = the length of the epithelium measured in a drawing made at ×100 magnification by projection. This figure was multiplied by 100 to delete the decimal fraction. All counts were made on 10 μ sections.

lens proteins are reduced. Accordingly pooled lots of (A) normal mouse lenses, (B) lenses from the cataractous strain showing incipient lens changes, and (C) advanced cataracts were used. Since the amount of soluble lens protein in these three groups was both small and unknown, a large number of mice were used, particularly of Group C.

The lenses were thoroughly ground in phosphate buffer pH 7.4 and the insoluble protein removed by centrifugation. The clear supernatant was used for analysis without dialysis or other treatment.* Nitrogen deter-

and the proportion each makes up of the whole is of importance.

Three major protein fractions were found in each sample of lens protein. The ratio of the quantity of these three in the normal, from the slowest to the fastest, is 2.6 : 1.0 : 1.3. When similar ratios were constructed for the early cartaracts a marked decrease in the amount of the slow component was immediately seen, 1.27 : 1.0 : 1.2. The pattern given by the proteins of the advanced cataracts also showed a marked reduction in the slow component, with no change in the other two, relative to each other.

Nitrogen determinations showed that there was 62.9 percent less soluble protein in the advanced cataracts than in the normal. The slow component forms 52.9 percent of the soluble lens proteins in the normal lens and is reduced to 34.7 percent in the advanced cataracts. It is evident, therefore, that, although this reduction accounts for a large measure of the protein loss, it cannot account for all of it. The middle and fast components are therefore affected about equally by some proteolytic process, but at a rate much

Some features of the cataract under discussion are reminiscent of posterior lenticonus.

Patry, quoted in Collin's article, commented on the apparent displacement of the lens nucleus to the posterior pole of the lens. A similar condition was noted in this strain of mice. However, the hyaloid vessels appear to play no rôle in the weakening and distortion of the posterior part of the lens as has been suggested that they may in man. The hyaloid system did not seem unusually
Fig. 13 (Smelser and von Sallmann). Electrophoretic patterns of the soluble proteins of (A) normal mouse lens, (B) early cataract, and (C) late cataract. The reduced size of the pattern in (B) is due to the amount of protein in the sample which was analyzed. The slow component is on the left.

slower than that attacking the slow component.

The reduction in quantity of the slow component in the advanced cataracts was 76 percent, of the middle 47 percent, and of the fast 48 percent. This effect on the proteins was marked even in the early stage investigated. The rates at which these three components moved in the electrophoretic field was not different in the several samples tested, indicating that the proteins present in the cataracts were the same as those found in normal lenses, although their proportion to each other and their quantity had been altered.

DISCUSSION

The cataract discussed here does not apparently have a counterpart which is common in man. E. Treacher Collins[1] described a few cases of posterior cortical cataract with rupture of the capsule at the posterior pole. Ziegler[2] described an hereditary posterior polar cataract which in the earliest stages seems somewhat similar to that studied here.

persistent in these mice and had disappeared entirely in all cases in which a rupture of the capsule had occurred.

The sequence of changes in these lenses was somewhat variable and marked differences sometimes occurred between the eyes of an individual. Completely normal lenses were found up to two months of age. Faint opacities were, however, detected as early as the 17th day of age and, in one case, as late as nine months. Dense opacities were usually present by 70 days of age. Vacuoles were not common until after the third month, by which time most of the lenses had ruptured and the nucleus had been extruded.

The occurrence of cholesterol in these cataracts is not surprising and has been reported in cases of hereditary cataract[3] The cholesterol appears late in the process and probably represents the end of a degenerative change rather than an early or an active phase.

The cause of swelling or even its occurrence has not been demonstrated in these studies, but the thinning of the capsule ap-

pears to be an early, definite morphologic change.

Electrophoretic analysis of normal beef, horse, and pig-lens proteins have been made by Viollier, Labhart, and Süllmann.[4] These analyses, carried out in veronal-acetate buffer, pH 7.9 with an ionic strength of 0.1 showed only two major components. Our analyses of normal mouse lenses clearly showing three major components of the soluble lens proteins were made in phosphate buffer at pH 7.4 with an ionic strength of 0.2. One additional analysis, however, was made with barbiturate buffer at pH 8.6 with an ionic strength of 0.1, which also revealed three components. The differences between the observation of Viollier and others and the present ones may be due to variation between the species or to the greater solubility of some proteins in salt solutions, since they used water in making the lens extract instead of buffer, as in our case.

It is impossible at the present time to identify the three components shown in the electrophoretic analysis of the mouse lens with the α and β crystalline or albumen found in other lenses by chemical methods. The relative vulnerability of one of the components (slowest) to the cataractous process recalls immediately, however, the studies of Krause,[5] who showed that β crystalline was rapidly attacked by proteolytic enzymes, in a slightly acid medium, whereas α crystalline was relatively stable.

SUMMARY

1. Morphologic changes, observed clinically and histologically, in a developing hereditary cataract have been described and compared.

2. The earliest observed changes involve slight disorganization in the posterior cortex and thinning of the lens capsule.

3. Decrease in the number of lens epithelial cells per unit area was noted in early cataracts.

4. Vacuolation of the lens and rupture of the capsule, thus discharging lens material into the vitreous cavity, were regularly observed.

5. The observation of iridescent crystals in the lens could not be well correlated with the demonstration of cholesterol histochemically.

6. Electrophoretic analysis of normal mouse-lens protein revealed three major components.

7. One lenticular component is reduced, in the formation of this cataract, at a rate nearly twice as great as that affecting the other components.

DISCUSSION

DR. WILHELM BUSCHKE (New York): I should like to ask two questions in relation to this very interesting presentation.

The first question has to do with the problem of reduction of cell divisions in the epithelium. Was there any reduction in the thickness of the lens at any stages preceding the actual cataract, as compared with control animals at a comparable age?

The second question is in relation to your

finding that the lens capsule was thin. Were there any histochemical changes in the lens capsule, particularly in relation to the sulfate polysaccharide, for example, with metachromatic staining? If so, it would be interesting to speculate about the possible connection of these changes with the skeletal changes, on the basis of a common biochemical factor.

DR. GEORGE K. SMELSER (New York): If I understood Dr. Buschke correctly, his question was on mitotic activity. There were some mitoses found, but we made no count of mitotic figures in the lens capsules of either the normal or the cataractous.

The number of cells present in the very early stages was reduced in the cataractous strain, but not by 25 percent; it was reduced on the order of 10 or 12 percent in numbers. I did not give the figures because I don't think one should give them undue emphasis, because they were based on rather few cases. These observations were made in animals prior to the development of a clinically observable cataract or a clinically observable abnormality. The thickness of the capsule was definitely less before there was any clinically observable abnormality.

DR. BUSCHKE: I meant the thickness of the lens.

DR. SMELSER: The whole lens? I cannot answer that, except in this sense: In histologic sections there was no change. I would not have too much confidence in measurements made on them. I would prefer to have the volume differences here. There was no obvious change in the sections. We made no histochemical studies on lens capsule. We hope to get some stimulation and ideas on that later today.

CYCLODIALYSIS*

I. A DISCUSSION OF TECHNIQUES

OTIS S. LEE, M.D. AND JAMES H. ALLEN, M.D.
Iowa City, Iowa

The modus operandi of the cyclodialysis operation for glaucoma, according to Heine's original concept,[1] was the establishment and maintenance of a communication between the anterior chamber and the suprachoroidal space. Proof that this communication persisted was furnished by Elschnig[2] in 1932 and Barkan[3] in 1947 from microscopic examination of sections of eyes in which successful cyclodialysis operations had been made but were removed post mortem. Further evidence in favor of this idea was found clinically upon gonioscopic examination by Barkan, Boyle, and Maisler[4] in 1936 and Burr[5] in 1947. The latter observer found that a cleft, indicating a separation of the ciliary body from its scleral attachment, could be demonstrated[†] in the chamber angle in all successful cases of cyclodialysis. The size of the cleft apparently had little to do with the degree of reduction of the intraocular pressure. As long as one was visible, the intraocular pressure was within normal limits.

According to Heine's description of his operation, an incision 3-mm. long was made through the sclera approximately 6-mm. posterior to, and parallel with the limbus. A spatula was inserted between sclera and ciliary body through the incision and passed into the anterior chamber to a depth of approximately 3 mm. The spatula then was

---

† Burr found that in some cases it was necessary to constrict the pupil with a strong miotic in order to view the cleft in the angle over the iris hump.
Fig. 1 (Lee and Allen). Heine's technique of cyclodialysis (after Blaskovics and Kreiker).

swept backward into the chamber angle (fig. 1). After breaking the attachment of the ciliary body to the scleral spur, it was then passed into the suprachoroidal space, first on one side and then on the other.

Blaskovics[6] pointed out that this method unduly traumatized the iris and ciliary body. It was possible for the spatula to tear through the base of the iris especially in cases with peripheral anterior synechias, or through the anterior portion of the ciliary body before breaking into the suprachoroidal space. This favored hemorrhage and post-operative iritis with stimulation of scar-tissue formation and subsequent obliteration of the newly created cleft thus sealing off the outlet for the aqueous humor from the anterior chamber into the suprachoroidal space. In order to minimize this, Blaskovics in 1935[6] introduced his modification which has become known as the inverse method of cyclodialysis (fig. 2). He reversed the Heine technique, separating the ciliary body from its attachment by sweeping the spatula from the suprachoroidal space into the anterior chamber. Thus, according to Shaffer,[7] the spatula followed a natural line of cleavage.

Since 1931, O'Brien[8] has been using and teaching a multiple thrust method of performing an inverse cyclodialysis. He made the scleral incision 5 mm. posterior to and parallel with the limbus. From this point he passed a spatula between sclera and ciliary body into the anterior chamber until the tip was just visible, then withdrew and re-inserted the tip into the chamber at progressively adjacent points, first to one side of the incision then to the other, until approximately half of the circumference of the ciliary body was detached from the scleral spur.

Although excellent results have been obtained by these last two techniques, annoying hemorrhages have still occurred occasionally and, when extensive, they have jeopardized the success of the operation. Therefore a slight modification of the O'Brien technique was made in an effort to reduce the incidence of hemorrhage even further (figs. 3a to 3c and 4).

ANATOMIC CONSIDERATIONS

The choroid and ciliary body are in loose apposition with the sclera except at three main points. The choroid is firmly attached to the sclera in the vicinity of the optic nerve
Fig. 2 (Lee and Allen). Blaskovics's technique of inverse cyclodialysis (after Blaskovics and Kreiker).
Fig. 3-a to e (Lee and Allen). Successive steps in the multiple-thrust technique of inverse cyclodialysis.

where the ciliary vessels pierce the sclera and also it is firmly attached to the sclera at the exits of the venæ vorticosæ posteriorly. The ciliary body is firmly attached only at the scleral spur anteriorly. Over the remainder of the choroid and ciliary body is the suprachoroidal space through which nonvascular lamellae of connective tissue run in all directions. The lamellae contain elastic fibers as well as pigment cells and are surrounded by endothelial cells, thus forming a maze of interconnecting endothelial-lined potential spaces called the suprachoridal lymphatic

Fig. 4 (Lee and Allen). Extent of excursion of cyclodialysis spatula indicated in solid black. Dotted line indicates line of attachment of ciliary body to scleral spur.

space of Schwalbe. The lamellae are fewer in the region of the ciliary body and steadily decrease from behind forward. The most anterior reaches of the suprachoroidal space immediately behind the scleral spur seem entirely empty.[9] The ease with which the choroid becomes separated from the sclera is illustrated by the large number of cases of choroidal detachment seen after cataract extraction.[10]

The blood supply of the uveal tract is derived from three sources: (1) The 10 to 20 branches of the short ciliary arteries

which enter the choroid around the optic nerve; (2) the two long posterior ciliary arteries, one traveling nasally and one temporally along the horizontal meridan between the choroid and retina to enter the ciliary body at its posterior border; and (3) the anterior ciliary arteries coming from the four recti muscles. There are two arteries from each except the lateral rectus from which there is only one. These vessels travel across the tendon insertions in the episcleral tissue to within 2 to 4 mm. of the cornea, then each sends a large perforating branch into the sclera passing through it perpendicularly to enter the ciliary body.

The venous drainage of the unveal tract occurs through the four venæ vorticosæ and the anterior ciliary veins which accompany the anterior ciliary arteries as they perforate the sclera.

TECHNIQUE OF CYCLODIALYSIS

1. CHOICE OF SITE OF OPERATION

This should be determined by gonioscopic examination of the chamber angle before operation, whenever possible. It is desirable to avoid dense anterior peripheral synechias and large blood vessels in the angle. In cases of glaucoma following cataract extraction the cyclodialysis should be made below to avoid the scar tissue.

2. PREPARATION OF OPERATIVE SITE

Usually either the superior or inferior temporal quadrant is chosen. Incision in the area immediately anterior to the superior rectus muscle as described by Blaskovics is not recommended because of the proximity of the anterior ciliary vessels. The sclera is bared by a short incision through the conjunctiva and Tenon's capsule. All visible episcleral vessels are cauterized with a thermal hot point. A scleral fixation suture is placed just anterior to the site of the scleral incision. It may be held either with a pair of forceps or a hemostat and the movement of the globe is thus controlled easily.

3. THE SCLERAL INCISION

In the Heine, Blaskovics, and O'Brien techniques the scleral incision is placed 5 to 6 mm. back of the limbus. Barkan and others[4] suggest that it be placed even further back in order to obtain a more extensive dialysis of the ciliary body. By placing the scleral incision 6 mm. or more back from the limbus, not only will it permit a sufficient length of spatula to be introduced into the suprachoroidal space to dialyze the ciliary body, but according to Salus[11] and Meller[12] it will also permit the spatula to section the nerves and vessels supplying the ciliary body as it sweeps through the suprachoroidal space, thus reducing formation of aqueous humor through atrophy of the ciliary body. Furthermore, should the ciliary body be injured while making the scleral section in this region, the less important nonvascular pars planum will be involved and not the more important pars ciliaris.

More recent studies, however, indicate that the disruption of nerve and blood supply to the ciliary body in the cyclodialysis operation contributes little if anything toward its success. In fact, rupturing the blood vessels should be avoided. Furthermore, one can dialyze half the circumference of the ciliary body without having to place the scleral incision farther back as recommended by Barkan and others, if one uses the multiple thrust technique of O'Brien instead of the sweeping techniques of Heine and Blaskovics.

Therefore, we prefer to place the incision approximately 3 mm. back from the limbus. By traction on the fixation suture, the scleral incision can be made safely, with danger of injury to the ciliary body reduced to a minimum. Traction on the suture actually lifts the sclera away from the ciliary body as the incision is being made.

4. THE CYCLODIALYSIS

By traction on the scleral fixation suture, the spatula can be introduced through the scleral incision into the suprachoroidal space with ease. After a very short distance, the spatula reaches the scleral spur. With firm but gentle pressure, keeping the spatula against the sclera, the dialysis is made and the tip of the spatula may be seen just within the inner margin of the limbus. It is slightly withdrawn and a series of short thrusts are made with the spatula always confined to the immediate region of the limbus and scleral spur. Approximately half the circumference of the ciliary body is separated from the scleral spur.

The cyclodialysis may involve the upper half, the lower half, or the temporal half of the ciliary body or, if the occasion demands it, the nasal half. The spatula is not permitted to enter the anterior chamber for more than 0.5 to 1 mm., nor is it swept backward into the suprachoroidal space. Its movements are limited to the immediate vicinity of the scleral spur. One need not fear performing a cyclodialysis past the horizontal meridan in order to avoid rupturing the long posterior ciliary arteries if one uses this technique. With the Heine or Blaskovics technique, one should avoid this region.

Even with the utmost care in technique and freedom from complications, there is a strong tendency for a narrow cyclodialysis to become reattached. The reason for performing a wide cyclodialysis is, then, not to obtain a large, filtering cleft but, by obtaining an extensive dialysis of the ciliary body, to reduce greatly the tendency for a complete reattachment, and to leave in a large percentage of cases, a small but adequate functional cleft in the chamber angle.

COMMENT

The purpose of the cyclodialysis operation is to permit internal drainage of the aqueous humor into the suprachoroidal space. This is accomplished when the attachment of the ciliary body to the scleral spur is severed. Further excursion of the spatula through the suprachoroidal space over the ciliary body

region is unnecessary since the ciliary body posterior to the scleral spur is in loose apposition with the sclera, and fluid can flow through this area without the help of instrumentation. This maneuver increases the amount of trauma to the ocular tissue.

Breaking of the perichoroidal lamellæ together with irritation of the ciliary body as the spatula sweeps over it might account for the severe iridocyclitis that sometimes follows a cyclodialysis operation. It certainly does result in a higher percentage of hemorrhages and more severe ones. Either of these conditions may be reasons for failure of the operation. Furthermore, in both the Heine technique and Blaskovics's modification, the spatula is carried into the anterior chamber for a considerable distance. This requires a skillful operator to avoid trauma to the iris and damage to the posterior surface of the cornea, especially when the chamber is shallow.

We are in full agreement with Barkan, Boyle, and Maisler that at least two fifths of the circumference of the ciliary body should be dialyzed to get the best results. O'Brien[13] recently has reëmphasized this and advocated approximately one half the circumference. However, one need not make the incision more than 3 mm. back from the limbus to accomplish this.

In cases with very shallow anterior chambers, we have performed a peripheral basal iridectomy together with the cyclodialysis. This additional procedure not only decreases the opportunity for formation of anterior peripheral synechias with resultant closure of the cyclodialysis cleft, but also frequently deepens the anterior chamber all around with its attendant advantages. Unlike the Wheeler[14] technique, a second incision is not necessary to perform the basal iridectomy. It can be made easily through the cyclodialysis incision since that is so near the limbus. In fact, to facilitate further the performance of the iridectomy, should this additional step be contemplated, the scleral incision should be made less than the usual 3 mm. back of the limbus.

SUMMARY

A method of inverse cyclodialysis is described in which the action of the cyclodialysis spatula is confined strictly to the region of the scleral spur. We believe this technique will reduce operative trauma with hemorrhages and postoperate irritation to a minimum and will increase the percentage of successes of the cyclodialysis operation.*

ANISEIKONIA FOR DISTANT AND NEAR VISION

KENNETH N. OGLE,* PH.D.
Rochester, Minnesota

AND

WENDELL TRILLER, B.S.
Hanover, New Hampshire

Can the aniseikonia for near vision be essentially different from that for distant vision? Although different measurements at the two distances are often found,[1] the questions to be answered are: to what extent are those differences significant and are they due to a basic difference in the aniseikonia or are they a peculiarity of the method of measurement? The answers are important, on the one hand, to the design of the eikonometer and, on the other, to the clinician who must reduce to a minimum the time needed for the aniseikonic examination. From the physiologic point of view significant differences would be important for their possible relation to changes in astigmatism, motility, and unequal accommodation from distant to near vision. Unless unequal changes in the optical systems or in the neurologic processes of the two eyes occur, it is difficult to account for other than small differences in the aniseikonia.

The partial unreliability of the measurements for near vision on the regular (direct-comparison) eikonometer, especially in the horizontal meridian,[2] has prevented a thoroughgoing study of the problem. With the development of the space-eikonometer technique, however, a means for a cross check with the regular eikonometer is now available. A definite clarification of the problem requires the study of a large number of cases, together with a study of the reliability of the space-eikonometer. At the moment, the data available on both of these studies leave much to be desired. However, the data on 115 subjects whose aniseikonic measurements had been taken on both eikonometers for distant and near vision are to be found in the files of the more recent cases of the Dartmouth Eye Institute. Since these data constitute evidence toward the solution of the problem, they are presented in this paper.

The descriptions of both the regular (direct-comparison) eikonometer and the space-eikonometer can be found in the literature and will not be given here. It is pertinent to review only the essential differences in the two instruments.

The earlier instrument depends on the patient's making a more or less direct visual comparison of the relative dimensions of the images of a suitable target as seen by two eyes.[3-6] The target (fig. 1), which makes use of plates of polaroid for separating the images seen by each of the two eyes, consists of light details, either projected on a metallic screen or presented in a transparency.

A configuration of a vertical and a horizontal line intersecting at a central circular disc is seen binocularly (unpolarized), while two systems of opposing lines (arrows) are so polarized that one is seen by the right eye, the other by the left eye. Thus, the right eye would see the lines associated with the odd numbers only, while the left eye would see those with the even numbers only.

Each pair of opposing arrows constitutes a vernierlike device and, if there is a difference in the sizes of the images between the two eyes, any two arrows will not be aligned but rather displaced with respect to each other. By suitable optical systems the relative magnifications of the images of the two eyes can be adjusted until the patient reports that the arrows on opposite sides of the central fusion disc are aligned or are equally dis-

---

placed (in case a marked fixation disparity exists).

The test constitutes, therefore, a direct comparison of the images seen by the two eyes. The sensitivity depends on the accuracy with which the fusion of the central patterns of the target is maintained, and on the visual acuity of each of the eyes. A fixation disparity, which is usually present if a phoria exists, may cause an equal displacement of the images of the arrows and may reduce somewhat the sensitivity.

The space-eikonometer[7-10] depends on

cords supported in front of and behind the cross and parallel to it. A central cord is usually suspended through the center of the cross. The two front cords subtend a visual angle to the subject of about 12°. Carefully adjusted apertures restrict the field of binocular vision to the test elements, which are evenly illuminated and viewed against a black cloth background. All empirical clues to depth perception are thus reduced to a minimum.

For near vision (40 cm.), the cords are replaced by strands of silk thread, accurate-
Fig. 1 (Ogle and Triller). The type of target regularly used in the direct-comparison or vernier eikonometer.

binocular stereoscopic spatial localization and on the fact that an aniseikonic error changes the usual disparity relationships between the retinal images of objects in space, with the resultant incorrect spatial orientation.[11,12] As schematically shown in Figure 2, the test detail is a space configuration, consisting, first, of an oblique cross made by a pair of intersecting cords stretched at right angles to each other and mounted in the frontoparallel plane; and, second, of two pairs of smooth vertical (to the visual plane)

ly mounted in a small box frame and attached to the eikonometer chassis. Experience has shown, however, that it is much more difficult to eliminate empirical clues to depth perception by this method at near vision, and the sensitivity of the test is found to be somewhat less than that for distant vision. However, if the test configuration is replaced by a "vectograph"[13] transparency of the same dimensions, those empirical clues are nearly eliminated and the sensitivity is only slightly less than that of

the test for distant vision. Most of the space-eikonometer data for near vision were therefore taken with the "vectograph" target.

Suitable optical systems permit the relative magnifications of the images of the two eyes to be adjusted, so that the several parts of the test configuration are perceived stereoscopically correctly oriented in space.

at one visual distance have not been an influencing factor in the measurements obtained at the other visual distance.

The 115 subjects included in this report were routine patients of the Dartmouth Eye Institute who had been referred for examination of aniseikonia. In many cases an additional spherical correction was needed for the near-vision tests. These additions were
Fig. 2 (Ogle and Triller). Schematic drawing of the space-eikonometer.

The method of limits is used to determine the aniseikonic errors.

The data presented here are from the case record files for patients who have been examined on both the direct-comparison eikonometer and the space-eikonometer for both distant and near vision. Measurements to be compared are those of the aniseikonic corrections for the horizontal and vertical meridians, and the declination error.[14-16] The data were obtained by three clinicians, one of whom obtained all of the data on the space-eikonometer. Obviously, it would have been better if the measurements for near vision could have been made by a different operator. It is hoped that the data

always equal spheres, carefully adjusted for equal distances from the eyes, and should not, therefore, of themselves introduce any changes in the relative magnifications of the dioptric images in the two eyes.

It is not feasible to present in this paper a table of all data obtained.* However, typical results are shown in Table 1. In this are given the refractive corrections used during the examinations, and the phoria for near vision is indicated because of its possible influence on the data of the direct-comparison eikonometer for near vision. Under the eiko-

_____

nometer headings are shown the percentage magnifications that had to be introduced before the eye indicated, in order to equalize the relative magnifications of the images of the two eyes. These data are for the horizontal (H) (axis 90°) and the vertical (V) (axis 180°) meridians. For the space-urements for distant and near vision, though less so in the horizontal meridian of the direct-comparison eikonometer, as might have been expected. For a more specific evaluation, it is necessary to study the variability between the measurements for distant and near vision of each instrument in

eikonometer the correction of the declination error, δ, is also given for distant and near vision. Unfortunately, it is not possible to indicate the precision of the data for each measurement, since this was not recorded on the data forms available. However, on the average, this was of the usual order of 0.25 percent to 0.5 percent magnification differences.

A cursory study of the data shows a reasonably close agreement between the meas-comparison to the variability or reliability of data obtained on the same instrument for both visual distances.

The quantitative relation between the distant and near findings for each instrument and each meridian is the slope of the line which best describes the data in a scatterplot diagram. Such a plot is shown in Figure 3, for data of the space-eikonometer for the horizontal meridian. In this figure, the measurements found for distant vision are plotted

along the abscissa, those for near vision along the ordinate. The slope of the line (which here will be called the mean regression line) best describing the location of the points is found by the method of least squares. For these data the sum of the squares of the distance of each point from the regression line has been minimized. The values of the slopes computed for the five sets of data are given in Table 2.

Other things being equal, one might expect on the average a 1 : 1 relationship between the two findings; that is, a measurement of one percent at distant vision would correspond to a measurement of one percent at near vision. Except for the direct-comparison eikonometer in the horizontal meridian, this 1 : 1 ratio is essentially realized, as an inspection of the table will show. Perhaps there is a tendency for the data for near vision to be slightly lower than those for distant vision. For the horizontal meridian in the exception noted previously, the near-vision data are substantially greater by 37 percent.

Because of the nearly 1 : 1 ratio, the standard deviation (which is the measure of variability) of the differences between the measurements for distant and near vision is also

a measure of the degree to which the near-vision aniseikonic error can be predicted by the distant vision measurements. That is, the standard deviation is the standard error of estimate of the data. On a percentage cumulative basis, 70 percent of the subjects had differences between the distant and near-vision findings less than that difference
Fig. 3 (Ogle and Triller). Scatter plot of the comparative eikonometer measurements in the horizontal meridian for distant and near vision—space-eikonometer.

TABLE 2

THE SIGNIFICANT STATISTICAL QUANTITIES WHICH DESCRIBE THE RELATIONSHIP BETWEEN THE MEASUREMENTS OF ANISEIKONIC ERRORS AT DISTANT AND NEAR VISION IN THE HORIZONTAL AND VERTICAL MERIDIANS

| | | Direct-Comparison Eikonometer | | Stereoscopic Space-Eikonometer | | |
		Horizontal	Vertical	Horizontal	Vertical	Declination
Slope of mean regression line:	Near / Distant	1.37	0.99	0.96	0.92	0.97
Standard deviation (n −d)		0.69%	0.54%	0.40%	0.50%	0.19°
Standard deviation for reliability	Distant	0.42%	0.36%	(0.3%)*	(0.4%)*	(0.2°)*
	Near	1.10%	0.60%	(0.5%)*	(0.5%)*	(0.3°)*
Pearson correlation coefficient		0.84	0.94	0.97	0.95	0.91
Means of data	Distant	0.06%	0.00%	−0.26%	−0.37%	+0.02°
	Near	0.91%	0.09%	−0.28%	−0.45%	+0.05°

* Estimated values.

defined as the standard deviation. The standard deviations for the five categories are given in the second row of Table 2.

The extent to which the near-vision data are correlated with those for distant vision is indicated by a comparison of the standard deviations found previously with the standard deviations of the repeatability or reliability tests of each instrument determined through repeated tests. For the direct comparison eikonometer such data exist.[2] They can at the present only be estimated for the space-eikonometer. These values are given in the third and fourth rows of Table 2. The estimated values were ascertained by a study of the stereoscopic sensitivities of subjects in the space-eikonometer under controlled conditions,[9] and of the correlation between the space-eikonometer and the direct-comparison eikonometer,[8] together with the standard deviations from the repeatability of the latter instrument.

While the Pearson correlation coefficient is difficult to interpret for the data of the type presented, it is given, also in Table 2, for what it may be worth.

A study of the table shows that, on the basis of the data available, the aniseikonic error at a near visual distance is essentially the same as that measured for distant vision, within the precision with which the measurements can be made.

One could not expect a good agreement between the findings for distant and near vision with the direct-comparison eikonometer because of the known poorer repeatability of the instrument for near vision. The means of the measurements for the near-vision test also show a marked bias. Since this did not appear with the distant-vision data nor for near vision in the vertical meridian, it probably cannot be due to an instrumental error per se. The means of the several sets of data also suggest that an error of about 0.25 percent magnification existed in the optical systems or targets of the space-eikonometer used in this experiment.

ENUCLEATION AND ALLIED PROCEDURES*

Part II. A Survey of Semiburied Implants†

JACK S. GUYTON, M.D.

Baltimore, Maryland

TRANSMISSION OF MOTION OF STUMP TO PROSTHESIS WITHOUT DIRECT ATTACHMENT

As early as 1917 Dimitry[194] designed a prothesis shaped like a Snellen reform eye but with a concavity in the posterior surface designed to clasp the stump by suction. He temporarily abandoned his idea because actual motility of the stump was not imparted to the prosthesis but, in 1942, he described deliberate creation of an elevated convex stump which would project forward far enough to fit into a prothesis with a posterior concavity of 11-mm. radius, and actually obtained a patent on this prothesis,[195] but he did not report any actual results.[196]

In 1940, Cutler[197] described the use of his "basket" type implant. This procedure afforded the first uniformly successful means of moving the prosthesis along with the stump. He implanted a cup-shaped acrylic framework, 15 mm. in diameter and 11 mm. deep, into Tenon's capsule, with its concave aspect anteriorly (fig. 1).

A double-armed suture was passed through holes in the bottom of the cuplike implant, out through the edges of Tenon's capsule and conjunctiva and through holes in a 5-mm. acrylic stud, rounded on the posterior end. Tenon's capsule and conjunctiva were next overlapped and firmly united by other sutures. The initial suture was then tied tightly enough to press the stud down into the basket, thus carrying Tenon's capsule and conjunctiva against the perforated acrylic framework so that, when healing was complete, a deep concavity with fairly rigid walls remained in the center of the freely movable stump. The prosthesis used after this operation had a smooth,

Fig. 1 (Guyton). Cutler's basket implant.

1725

somewhat cone-shaped projection on its posterior surface which would fit into the concavity of the stump and thus acquire motility (fig. 2).

Cutler reported excellent results in 50 enucleations performed with his basket implant. This procedure was a tremendous advance over previous procedures, and it would undoubtedly have attained very wide-

Fig. 2 (Guyton). Prosthesis used after insertion of Cutler's implant.

spread use had not semiburied implants been introduced very shortly afterward.

SEMIBURIED IMPLANTS WITH DIRECTLY ATTACHED PROSTHESES

RUEDEMANN'S PLASTIC EYE IMPLANT

In 1941 Ruedemann[198] conceived the idea that a prothesis made of acrylic and shaped like a whole eyeball might serve as a permanent, nonremovable substitute for an enucleated eye if inserted into Tenon's capsule, the rectus muscles attached, and the anterior portion (shaped and colored to match the fellow eye) left exposed. The possibility of a nonviable structure with direct attachment to living, subepithelial tissue remaining permanently partially buried and partially exposed, with a consequent line of transition between epithelium and subepithelial tissue in the lining of the structure, is a natural occurrence in the case of teeth; nevertheless, Ruedemann's application of this principle to prostheses was completely original not only in the field of ophthalmology, but in surgery as a whole.

Ruedemann began implanting whole acrylic eyes into Tenon's capsule in 1941, and, in 1945, he first reported this procedure[1] before the American Ophthalmological Society. He had by that time performed over 100 such implantations. When he first began performing this operation, he used various sized and shaped eyes, "mostly wrong," and attached the eye in place with various suture materials and techniques, "also mostly wrong." However, by "trial and error plus much effort" he obtained more and more successful results, and implanted artificial eyes exhibiting normal motility and without retraction of the upper lid sulcus. He also had successes with delayed implantations into deformed sockets, using fibrous tissue for attachment if the recti could not be identified.

When Ruedemann first reported his operation, the technique he preferred was to attach the severed ends of the recti to perforated tantalum paddles by fine tantalum wire sutures, which were then attached to the plastic eye (figs. 3 and 4). The plastic eye matched the fellow eye in coloring and size. He listed the following complications: dyes fading, muscles coming loose, conjunctival discharge if conjunctiva retracted so as to expose tantalum suture or paddle, strabismus and ptosis if the eye was set too deeply in the orbit.

In May, 1945, Dr. Alan Woods visited Dr. Ruedemann in Cleveland and watched him implant two of his plastic eyes, and also examined a number of patients who had already undergone such an operation. Dr. Woods was so impressed he obtained Dr.

Ruedemann's permission to utilize this procedure, and he inserted the first of these implants at the Wilmer Institute in June, 1945. Between June, 1945, and December, 1945, 10 of the Reudemann implants were inserted. Nine were used at the time of

ing operation, the average period between operation and extrusion being 10 months. These extrusions apparently resulted from contracture of the fairly dense fibrous sheaths around the buried portions of the implants and from retraction of the con-
Fig. 3 (Guyton). Ruedemann's original plastic eye implant.

enucleation and one after removal of a displaced gold-ball implant. The initial results were excellent in four of these patients, there was appreciable tropia in five, with some persistent ptosis in three. In the remaining patient insertion of too large an implant resulted in immobility of the eye. One patient developed orbital cellulitis three months after an initially successful operation.

Nine of the implants were extruded at intervals of seven days to 22 months follow-

junctiva from the ends of the rectus muscles which eventually, despite repair, broke free from their attachments to the tantalum clips. One implant was still in place 29 months after operation, but there was some exposure of the paddles and attached muscle ends.

In a recent personal communication,[198] Ruedemann stated that every one of the
Fig. 4 (Guyton). Attachment of muscles to Ruedemann's whole acrylic eye via tantalum paddles.
Fig. 5 (Guyton). Ruedemann's modified acrylic eye implant, with tantalum mesh for attachment of tissues.

plastic eyes he had implanted with muscles connected to tantalum clips was eventually extruded or had to be removed. Nevertheless, the eyes stayed in place long enough to suggest that improved techniques might result in permanently successful implantations.

As early as November, 1945, Ruedemann proposed utilizing a whole eye implant with tantalum mesh surrounding the buried portion,[199] and soon thereafter he began implanting such eyes (fig. 5).

The rectus muscles and the edge of Tenon's capsule were simply sutured to the anterior border of the mesh, with the sutures also passing through holes drilled through the plastic. Tenon's capsule and the muscles became firmly adherent to the tantalum mesh. When it was necessary to straighten the eye after it was implanted, Ruedemann found it difficult to separate muscles and Tenon's capsule from the mesh-work, but he has done so by means of a periosteal elevator. Since adopting this never type of implant, he has had only a few extrusions, which he thinks probably resulted from using too large a size.

scribed the first implant of this type (January, 1947) as "a positive contact ball and ring implant."[2] This ring implant consisted of an acrylic sphere with a short anterior cylindrical prolongation surrounded by a gold or vitallium ring attached to the plastic by four equidistant metal bars, and with a metal cup inset in its anterior surface (fig. 6). The ring implant was inserted following simple enucleation by folding the ends of the recti around the ring from within outward, folding Tenon's capsule and conjunctiva over the ring in the opposite direction, and suturing

Fig. 6 (Guyton). Cutler's ring implant.

these structures firmly in position with non-absorbable sutures (fig. 7).

After the socket was completely healed, a prosthesis was made to match the visible anterior segment of the other eye in size and color. This prosthesis was similar to acrylic prostheses worn after simple enucleation except that the scleral portion was smaller and more curved, so as not to extend into the fornices. A metal pin which fitted snugly into the cup of the implant was attached to the back of the prosthesis, the pin being positioned on the prosthesis so that the eyes were in perfect alignment. The pressure of the lids held the pin in its cup and produced firm attachment of the prosthesis to the implant so that full motility of the implant was conveyed to the prosthesis.

The use of this male-female coupling eliminated the necessity of inserting a whole

CUTLER'S RING IMPLANT WITH ATTACHABLE PROSTHESIS

In October, 1945, Cutler began inserting buried implants to which protheses could be coupled after the socket had healed. He de-

eye implant, which had to be individually made prior to operation and therefore could not be used for emergency enucleations. The coupling permitted construction and adjustment of the prosthesis after healing occurred, insured perfect alignment and position, and allowed for replacement of prostheses if they became faded, scratched, or otherwise imperfect. Cutler's introduction

by Cutler the follow-up was limited to only a few months. In a recent personal communication, Cutler[200] stated he was gathering follow-up statistics but that these were not yet complete. "The longest follow-up I have a record of is 2½ years; incidentally this patient has not had his prosthesis out during the past year and a half. None of my original implants put in since April, 1946,
Fig. 7 (Guyton). Cutler's ring implant sutured in position.

of this two-piece principle was a notable step in the attainment of uniform final results.

Cutler reported the use of his ring implant in 22 patients. Five implants had to be removed. Three of these were the first he had used and were constructed of three pieces screwed together; in one case the patient developed orbital cellulitis and pneumonia six months after the implant was inserted; in the other two cases, the ring became exposed by erosion through its covering of Tenon's capsule and conjunctiva, and this led to a gradual increase in the exposure of the ring and the eventual detachment of the muscles. Cutler noted that attempts to repair the covering of a partially exposed ring were fruitless.

In the group of cases originally reported

have come out. I haven't done many secondary operations. However, I think one half have come out for various reasons and the other half are doing very well."

In June, 1946, O'Brien, Allen, and Allen[201] reported having inserted a few implants like those of Cutler into Tenon's capsule. They modified Cutler's original design slightly by substituting bridges across grooves for the ring. The recti were split after passing under the bridges and sutured together around the anterior peg rather than folded back on themselves. The few implants inserted during the six months preceding their report gave encouraging results. However, in a recent personal communication about semiburied implants, O'Brien[202] said, "I did make a preliminary report in San Francisco several years ago but I am not as enthusiastic

as I was at that time. It seems to me there remains a great deal to do before these things are satisfactory."

At the Wilmer Institute, 23 Cutler ring implants were inserted between March, 1946, and March, 1947. Two of these were reimplantations, one at the time a Ruedemann whole eye implant was extruded, and the other 15 days after extrusion of a previ-
Fig. 8 (Guyton). Hughes's hollow vitallium ring implant.

ous ring implant. Both of these reimplantations were extruded within four months. Of the 21 ring implants inserted at the time of enucleation, seven were still in place and gave excellent cosmetic results after follow-up periods of 1 to 11 months (average five months). Fourteen were extruded at intervals of one day to 11 months (average five months) after insertion.

The events leading to extrusion were exactly the same as those originally noted by Cutler: exposure of a small segment of ring, usually in its upper portion, and gradual extension of this defect, with eventual detachment of the muscles. We likewise found, as had Cutler, that attempts to repair a defect over the ring were uniformly unsuccessful. However, in all fairness to the ring implant, it must be recorded that these

operations were performed by a number of different surgeons, who in some instances did not follow the exact technique of suturing advocated by Cutler, and that the implants we used had slightly less space between the ring and body of the implant than Cutler believed desirable. Also, the attachable prostheses used with the first implants were too flat and too large, so that attempted maximal rotation resulted in a strain on the attachments surrounding the ring.

Hughes[49] began inserting slightly modified ring implants into Tenon's capsule in October, 1946. His modification consisted of an implant made of hollow vitallium rather than of plastic, with the ring closer to the implant and attached by eight bars instead of four (fig. 8). The diameter of the buried portion was approximately 18 mm. if it was to be used immediately following enucleation, and 12 mm. if designed for the replacement of a buried implant.

His technique for initial implantation included preservation of strips of sclera in front of the insertions of each of the recti, 3 or 4 mm. in length and two thirds of the thickness of the sclera, thus extending the length of the rectus tendons so they would be sufficiently long to pass around the attachment ring without being under tension. For replacement of a buried implant, Hughes thought the ring implant feasible only if the buried implant was approximately in normal location with good motility and with enough connective tissue attached to the recti to fold over the ring and permit adequate attachment. Initial good results were obtained in the four cases described in his preliminary report, but all four operations had been performed within the preceding four months. In a recent personal communication, Hughes[203] cited some nice results with the late replacement implants, as well as with those inserted at the time of enucleation.

Cusick[204] has inserted 10 Cutler ring implants (nine primary and one secondary)

since October, 1946. The first one he inserted was extruded following gradual exposure of the upper portion of the ring after about two months. In his subsequent operations, he paid considerable attention to overlapping the upper structures more extensively than the lower ones, thus providing a relatively thicker covering for the upper portion of the ring, and he has had no more extrusions. He is probably correct in believing this manuever was responsible for his subsequent good results. Cooper[205] has had no extrusions of three ring implantations six months after the operations.

Rosen[206] has recently described as original an implant having the same slight modification which O'Brien, Allen, and Allen, first reported in June, 1946.

The present status of Cutler's ring implant may be summarized as follows: It is the first semiburied implant with a detachable prosthesis, and represents a distinct advance in enucleation procedures. Furthermore, if the ring implant is properly made and is inserted with careful technique and with wide overlapping of Tenon's capsule (especially above), the cosmetic results are not only initially excellent, but will probably be permanent in a majority of cases. This implant is seldom suitable for delayed implantations.

O'BRIEN'S SEMIBURIED EVISCERATION IMPLANT WITH ATTACHABLE PROSTHESIS

In the June, 1946, report of O'Brien, Allen, and Allen[201] already cited, the authors also described use of a few semiburied intrascleral implants, which they originated. The first of these gave excellent initial results but became gradually extruded. A change in the size of the implants and in the technique of insertion was made after the first few extrusions, and the implants they then inserted seemed less likely to extrude.

The implant in use at the time of their report consisted of an acrylic ellipsoid, 11.7 by 14 mm., with a short cylindrical peg 4

mm. in diameter extending forward from its anterior surface, and a plastic flange which could be fastened around this peg after the implant was inserted. The anterior surface of the peg was inset with a round cup for the reception of the pin of the attachable prosthesis. To insert this implant, a 4-mm. hole was trephined through the center of the cornea, a meridional incision 18 to 20 mm.
Fig. 9 (Guyton). Hughes's hollow vitallium evisceration implant.

long was made through the upper temporal sclera, the contents of the globe were eviscerated, the implant was inserted so that the peg protruded through the hole in the cornea, the scleral incision was closed and the flange around the peg fastened to prevent its slipping back through the cornea. No long-term results were available at the time of the preliminary report, and O'Brien[202] is not now as enthusiastic about these implants as he was in 1946.

Hughes[49] began using evisceration implants resembling those of O'Brien, Allen, and Allen as well as ring implants in October, 1946. His evisceration implants were made of hollow vitallium, and his later models had two small bridges through which strips of sclera could be passed for firmer attachment (fig. 9). His technique involved removal of the entire cornea. A preliminary report included four cases of evisceration with these semiburied implants. Two of the

implants were extruded within the short follow-up period, and a third case had to be reoperated. In a recent communication Hughes[203] said that he made some changes in the design of the implant, using two different sizes, and that he is now carrying out further investigations in this line.
Fig. 10 (Guyton). Whitney and Olson's acrylic implant with tantalum mesh belt for attachment of recti and Tenon's capsule.

In summary, it may be fairly concluded that this type of evisceration implant has thus far proved disappointing.

SEMIBURIED ACRYLIC IMPLANTS PARTIALLY COVERED WITH TANTALUM MESH

In August, 1946, Whitney and Olson[3] first inserted a semiburied implant partially surrounded with tantalum mesh and adapted for an attachable prosthesis. This first implant was an acrylic ellipsoid, 18 by 20 mm., covered except over the slightly protruding anterior face by fine tantalum mesh (fig. 10).

After two of these implants had been inserted, Whitney and Olson decided that better motility would result if the posterior surface of the implant were left smooth and the sides of the implant covered with mesh.

This decision was based on the observation of two sockets in which buried doughnut-shaped implants of fine tantalum wire had been inserted the previous year: the stumps were initially freely movable, but after some months the motility gradually diminished, the position of the stumps apparently becoming "fixed" by extensive fibrosis.

One implant with a smooth posterior surface was inserted in October, 1946. Between September, 1947, and March, 1948, they inserted 10 additional implants which differed only in having a narrower rim of tantalum mesh, a groove around the anterior portion of the implant beneath the mesh, and a larger, shallower cup to serve as the female coupling (the small, deep cup first used had collected an odoriferous discharge). All of these implants were inserted at the time of enucleation. Thus far none have extruded, and the results have been excellent. The only complaints Whitney and Olson make are that some sockets have had more discharge than after simple enucleation, and that in some cases there is actual hypermotility of the prostheses.

In March, 1947, Stone[207] began insertion of implants (fig. 11) almost exactly like those of Whitney and Olson, and in October, 1947, he reviewed the results of 20 initial
Fig. 11 (Guyton). Stone's acrylic and tantalum mesh implant.

implantations and four delayed implantations. There were no extrusions, and the motility of the implants varied from 50 to 100 percent of normal. The only complications were conjunctivitis in three cases.

In a recent communication, Stone[208] noted that there were as yet no extrusions. In two cases where reoperation was performed to obtain better motion from individual muscles he found "the fibroblastic proliferation of Tenon's capsule and the retrobulbar fat was so firm that it was impossible to separate it from the meshwork with a spatula. It was also so coarse that cutting with scissors was difficult. The conjunctival epithelium had firmly engaged itself at the anterior edge of the meshwork and it was also impossible to separate this junction with a spatula."

Since May, 1947, Cutler[200] has used an implant (fig. 12) similar to that of Whitney and Olson, in preference to his original ring implant. He terms this newer implant the "universal type," for use in enucleations, reimplantations, and his enucleo-evisceration operation (preservation of a scleral ring containing the attachments of the rectus muscles). He says "about 25 or 30 have been used since May, 1947, in Wilmington. One secondary came out after about five days in the hospital because I discontinued the pressure dressing in a patient who had a hemorrhage. I didn't think it *could* come out—but it did. The Gougelman Company up to 2 or 3 weeks ago, had sold, I believe, about 150 of these. No expulsions are known to them. ... The use of the mesh implant is short and simple. Catgut sutures only are used." (Whitney and Olson, and also Stone, prefer sutures of fine tantalum wire.) Cutler has found the range of movement with this type of implant is approximately the same as that with his original ring implant.

In summary, this Whitney-Olson type of semiburied implant appears to be better than any of those previously described. A considerable number have been implanted

during the past 12 months with consistently excellent results. However, it is well to remember that, with this as well as with other semiburied implants, "the theoretical disadvantage of the procedure is great. It controverts basic surgical dictum that a wound must be completely epithelized in order not to break down. Not only is the wound seemingly not epithelized, but there has also been introduced a foreign body which is not epithelized. When an analogous pro-
Fig. 12 (Guyton). Cutler's "universal" acrylic and tantalum mesh implant.

cedure has been attempted in the past by dental or orthopedic surgeons, no matter how small their unepithelized pin might be, sloughing invaribly has ensued."[207]

It seems probable that the excellent results so far obtained with tantalum-mesh attached implants will be permanent; but only long-term follow-ups can eliminate the possibilities of gradual late restriction of motility because of too heavy proliferation of fibrous tissue around the implants (such as noted by Whitney and Olson with buried implants of tantalum wire) or of late orbital infections occurring because of lack of epithelialization around the implant.

(To be concluded.)

THE NONSURGICAL TREATMENT OF HETEROTROPIA*

RICHARD G. SCOBEE, M.D.

Saint Louis, Missouri

There are three objectives which may be attained by nonsurgical therapeutic means in the patient with heterotropia. They are: (1) The destruction of abnormal retinal correspondence, (2) the abolition of suppression amblyopia, and (3) some adjustment of the accommodation-convergence reflex. When these three objectives have been reached, the final goal in the treatment of all patients with heterotropia—fusion—may often be obtained in a surprising number of cases. The three objectives will be considered in the order mentioned.

ABNORMAL RETINAL CORRESPONDENCE

Corresponding retinal elements are those which have the same visual direction. In the person whose eyes are normal and who has normal retinal correspondence, imagine some object, O, located straight ahead as the object of gaze. The image of O will fall on corresponding retinal points in the two eyes. Any object whose image falls at A in the

right eye will be projected back into space to the point O and the same will be true of the point B in the left eye. Since A and B have the same visual direction, they are said
Fig. 1 (Scobee). Diagram showing corresponding retinal points.

to be corresponding retinal points. This is shown in Figure 1.

A person with esotropia, for example, has an entirely different situation, as shown in Figure 2. O is again the object of gaze of the right eye and the image of O falls at A; the left eye, however, is turned inward in esotro-
Fig. 2 (Scobee). Diagram showing abnormal retinal correspondence (esotropia).

pia and the image of O falls not on B but on the point Z.

In Figure 1, A and B, representing the two foveas, are seen to be corresponding points. In Figure 2, O is forming an image at A and at Z; A and Z are obviously not corresponding points because any object imaged at A will be interpreted as being straight ahead while any object imaged at Z will normally be interpreted as being located to the left of the midline.

Since the patient has esotropia, however, every time he looks at the object O, it is imaged at A in the right eye and at Z in the left eye. After countless repetitions of this situation, the patient finally learns to interpret images falling at Z as being straight ahead instead of to the left! A and Z have now become corresponding retinal points in that they have the same visual direction. A and B are normally corresponding retinal points and yet A and Z have developed an abnormal relationship of correspondence and the patient is said to have abnormal retinal correspondence.

The therapeutic problem in such a case is obviously first to destroy the abnormal relationship between A and Z and, secondly, to reëstablish the proper relationship between A and B.

Abnormal retinal correspondence is a conditioned reflex which has developed in response to a conditioning stimulus. Every time the patient looks at any object with the point A of his right eye, the point Z in the left eye is also stimulated and the relationship between A and Z is strengthened. If one would destroy a conditioned reflex, one must completely remove the conditioning stimulus. If the fixation of the objects with the right eye (actually, with the point A of the right eye) is the conditioning stimulus and the conditioning stimulus must be removed, then the fixation of objects with the point A of the right eye must be prevented at all costs. In other words, the right eye must be constantly occluded and thus prevented from fixing on any object at all.

Once the right eye is prevented by occlusion from assuming fixation, the left eye is forced to take up the task. The spot of greatest potential retinal sensitivity in the left eye is B, its fovea, even though it has not been used because of the abnormal position of the left eye in esotropia; the point Z in the left eye has been used in this instance as a matter of necessity. Once it is no longer necessary to use Z, the left eye will prefer to use the point B because B is

far more sensitive, potentially, than is Z. When Z is no longer used in conjunction with A, the abnormal relationship between these two abnormally corresponding points begins to weaken and will eventually disappear in most cases. Meanwhile, B—the normally corresponding point of A—is being used continuously. After the abnormal relationship between A and Z has been destroyed, the patient is free to develop a normal relationship between A and B provided the eyes can be held in such a position that this is possible.

While the foregoing paragraphs are somewhat of an oversimplification of the actual situation, nevertheless the idea as a whole is sound and should serve to clarify the problem. There is no question but that complete and constant occlusion of the nondeviating eye in the patient with heterotropia is the first and most important step in the destruction of abnormal retinal correspondence.

SUPPRESSION AMBLYOPIA

This may be defined as the apparent loss of vision in the crossing eye which develops in patients with monocular heterotropia. In the past, this visual loss has been somewhat erroneously called amblyopia ex anopsia or the blindness of disuse. In the first place, the visual loss is not a blindness of disuse because it does not occur in the retina itself but instead is localized at the level of the occipital visual cortex and is believed to occur as a result of active suppression in that area.

Suppression amblyopia occurs as the result of a conditioned reflex in the same way that abnormal retinal correspondence develops. It would not be incorrect to think of the two as developing simultaneously. To return to Figure 2, the patient is fixing an object O with the point A of the right eye; the deviating left eye has the point B (the normally corresponding point with A) aimed at some other object, X.

If the patient is to keep from seeing X and O superimposed at the same point in space—an impression which would obviously be very confusing—then the image falling either at A or at B must be ignored by the brain. The image falling at B, that is, the image falling at the fovea of the deviating or crossing eye, is the one which is invariably ignored and it is more than a passive inattention toward images falling at B; it is an actual suppression which is active and certainly not passive.

One cannot merely ignore a stick of dynamite with a lighted fuse lying nearby if one expects to continue in the efficient performance of the daily tasks of living; the fuse must be extinguished—in short, something active must be done about the situation.

The brain in actively ignoring images falling at B is "doing something" about the situation. Every time the patient looks at an object, such as O, with the point A of the right eye, the brain must ignore whatever object (such as X) that may happen to cast its image at B in the crossing left eye.

Thus, the stimulus for suppression in the brain connected with the point B in the left eye is the use of the point A in the right eye for fixation. Each time the patient looks at an object with A in the right eye, the point B in the crossing eye must be suppressed a little bit more. Suppression amblyopia is a conditioned reflex and the conditioning stimulus is the use of the point A in the nondeviating eye.

It has already been shown that the use of this same point A in the nondeviating eye is also the stimulus for the development of another conditioned reflex—that of abnormal retinal correspondence. As in this former instance, the treatment of suppression amblyopia is the destruction of the conditioned reflex which is responsible for its existence. This means removal of the conditioning stimulus.

The conditioning stimulus is easily eliminated by merely occluding the right eye and thus preventing the stimulation of the point A. This procedure forces the use of the left eye and its area of potentially greatest sensi-

tivity, the point B. With A out of the picture, there is no longer any need for the brain to ignore B but instead there is an actual demand for the recognition of objects falling at B. Thus may suppression amblyopia, a conditioned reflex, be destroyed by removing the conditioning stimulus, the latter being accomplished by occluding the habitually fixing eye.

It may now be appreciated that occlusion of the nondeviating eye in the patient with monocular heterotropia accomplishes two purposes simultaneously: (1) The disruption of abnormal retinal correspondence, and (2) the destruction of suppression amblyopia. In both instances, we have a conditioned reflex which is abolished by removal of the conditioning stimulus. In each case, the conditioning stimulus is the fixation of objects by the noncrossing eye. If a conditioned reflex is to be thoroughly abolished, the conditioning stimulus must be completely removed. This calls for constant and complete occlusion of the good or habitually fixing eye until both goals have been attained.

It is to be emphasized that wearing a patch over the habitually fixing eye for a few hours a day is not constant occlusion and is almost worthless. A conditioned reflex is extremely difficult to destroy if the conditioning stimulus is removed for only a few hours a day and is then allowed to act during the rest of the waking hours.

Atropinization of the better seeing eye instead of occlusion of that eye is of little value; the patient will continue to use the atropinized eye for distant fixation and use the poorer eye only for near objects.

A minimum trial period of six months of constant and complete occlusion should be insisted upon in every case. If the occlusion has been faithfully carried out and there is no improvement in vision at the end of this period, the occlusion may be discontinued and a tentative diagnosis made of congenital amblyopia.

Of the various types of occluders available on the market, the most satisfactory is the flesh-colored elastoplast patch. It is impossible for the patient to "peep" with this type of occlusion.

The patient with the better eye occluded should be encouraged to look at large, colored picture books, to play with large, brightly colored toys, especially large balls. The cheiroscope is an ingenious and useful instrument in stimulating the use of the poorer eye. Ruedemann has suggested the use of a kaleidoscope in these patients and the idea works well in practice; it is particularly important that the toy be held aimed at a sufficiently bright light source in order that the rapidly changing pictures may be properly illuminated.

ADJUSTING THE ACCOMMODATION-CONVERGENCE REFLEX

All of the remaining nonsurgical therapeutic measures in heterotropia may be gathered into this general classification. Included are the use of glasses, prolonged atropinization, prohibition of close work, certain forms of orthoptics, and more recently, the use of pilocarpine, eserine, and even of D.F.P. They will be discussed in the order named.

1. *Glasses.* Correction of any existing ametropia is the first step and an important part in the therapy of heterotropia because the majority of cases have an accommodative element, no matter how small. Because hypermetropia leads to compensatory accommodation and an associated excessive convergence, any hypermetropia found in patients with esotropia should be fully corrected; if exotropia is present and there is hypermetropia, only the minimum correction needed to secure clear vision is advisable. When myopia is present and there is esotropia, only the minimum correction needed to secure clear vision should be given; on the other hand, if there is exotropia and myopia, a very full or even a mild overcorrection of the myopia is indicated. Astigmatism, irrespective of type, should always be fully corrected, regardless of

whether the lateral deviation is one of eso-tropia or exotropia.

A word about what is meant by a "full" correction is necessary. A full correction means the entire refractive error as found under atropine cycloplegia. If a patient has esotropia and is found to have 4.25 diopters of hypermetropia, the full 4.25 diopters should be given in the prescription, deducting nothing for ciliary tone.

It is rare that one obtains complete cycloplegia in a child, even with atropine, and hence what appears to be a full correction is usually an actual undercorrection by an amount equal to the incompleteness of the cycloplegia. The deduction of even 0.5D. from the atropine findings will sometimes make a difference of as much as 10 degrees in the amount of deviation corrected by glasses.

We have discontinued entirely the use of atropine as an eyedrop in children and even adults with heterotropia for two reasons: (1) The cycloplegia is often incomplete because either tears quickly flush much of the drop from the sac or dilute it to a point where it is relatively ineffective, and (2) systemic reactions are frequently encountered in children.

In place of the atropine drop, atropine ophthalmic ointment (0.5 or 1 percent) is routinely used. Systemic reactions with the ointment are very rare and the ointment results in a higher concentration of atropine in the sac over a longer period of time, thus leading to much better cycloplegia.

If a parent has difficulty in getting any medicine into the child patient's eyes, the ointment is superior to the drop because even though it only gets on the lashes, it soon melts and runs into the eyes. The ointment is used three times daily for a minimum of three days prior to refraction.

A full correction is prescribed, no matter how small the error that is found, and the glasses are then worn constantly for a minimum of one month before any judgement of their effect in reducing the deviation is

attempted. The one-month interval is absolutely essential in order that the patient may establish a new accommodation-convergence ratio.

The routine just described often seems to work a hardship on the out-of-town patient and many oculists are wont to skip it in such instances. Their final results are proportionately bad. While such patients may at first seem to object, their final reaction is invariably one of satisfaction, the thought seemingly uppermost in their minds being that the doctor was thorough.

The occasional child who complains of blurred vision with his full correction will need to be atropinized by the use of the ointment once or twice daily for about two weeks.

A not uncommon occurrence is met with in patients whose esotropia is fairly well controlled by correcting lenses. They may suddenly seem to develop more esotropia in spite of the glasses. This is almost invariably an indication that the glasses need changing. These patients will be found to have outgrown a certain portion of their hypermetropia and a reduction in the amount of the plus sphere in their correction will, paradoxically enough, produce a corresponding reduction in the amount of esotropia.

The paradox is easily explained, however, when one recalls that a hypermetropic eye that is overcorrected—as is one that has outgrown some of its hypermetropia when the glasses are not changed—is an eye with blurred vision. The response to blurred vision is always an attempt to further accommodation with its associated convergence. Hence when vision blurs, the patient attempts to accommodate more in order to clear it and incidentally converges more in the process, thus increasing the esotropia.

Reducing the plus correction to the proper amount results in a return of clear vision and a decrease in the efforts at accommodation and incidental convergence.

2. Atropinization. Children with esotropia or marked esophoria will frequently be bene-

fited by from 3 to 6 weeks of atropinization during and immediately following systemic illnesses. The reason is obvious. The tonus of the bodily musculature as a whole is below par and the ciliary muscle is included. Excessive accommodative demands are needed in order to perform close work and excessive convergence automatically ensues.

Atropinization is also of value in high-strung children with esotropia normally corrected by glasses when they are undergoing periods of stress or strain, such as beginning school. Guibor advocates phenobarbital in small doses in such cases and it may indeed be of value in quieting a hypertonic convergence center associated with a tense central nervous system.

3. Prohibition of close work. The intelligent and high-strung child with esotropia will show an apparent increase of that esotropia during periods of stress. When this occurs, it is wise to prohibit all close work for a month, two months, or even three months. The goal of such prohibition is, of course, prevention of use of the eyes as much as possible during periods of actual esotropia and thus preventing both suppression and abnormal correspondence from developing. A child that is just on the borderline of fusion—fusing at times and at other times lapsing into tropia —should be prohibited from casual close work and confined to supervised orthoptics.

4. Orthoptics. Certain forms of orthoptics are aimed at adjusting the accommodation-convergence reflex. The goal is usually an attempt at at least a partial dissociation of accommodation and convergence. It is not within the scope of this paper to present the means by which this may be accomplished but it can be done successfully in many instances with gratifying results.

5. Pilocarpine, eserine, and D.F.P. Abraham* reports a series of cases whose treatment was based on an ingenious theory. He used miotics in patients with intermittent esotropia and reported good results in a surprisingly high percentage of such cases. He reasoned that miotics produced ciliary spasm which he chose to call "peripheral accomodative spasm" (as opposed to central accommodative spasm such as might occur in hypermetropia in response to a demand for clear images by the brain).

If such accommodation were produced artificially and peripherally, then there should be no demands centrally for accommodation and hence no associated convergence. Thus did Abraham explain the apparent beneficial effects of miotics in patients with intermittent esotropia. Attempts at confirmation of his work are not yet completed. The idea is a fascinating one for speculation, however.

SUMMARY

The nonsurgical measures in the therapy of heterotropia have been considered. Although approximately 60 to 70 percent of all patients with heterotropia require surgery before a final cure may be effected, still the remainder may be cured by nonsurgical measures properly employed. Many of the nonsurgical measures enumerated are important prerequisites of surgery in any event and it is well for the ophthalmologist who would treat patients with heterotropia to be fully cognizant of them all.

NOTES, CASES, INSTRUMENTS

VITREOUS LESIONS OBSERVED IN BOECK'S SARCOID*

PHILIP H. LANDERS, M.D.†
Binghamton, New York

The purpose of this report is to describe vitreous lesions found in five eyes in a series of 13 patients having sarcoidosis who were observed at the Veterans Administration Hospital at Fort Howard, Maryland, during a two-year period ending July 1, 1948. A complete study from the ophthalmic viewpoint of the cases of sarcoidosis from this hospital, including the results of nitrogen-mustard therapy in selected cases, will be submitted at a later date.

Sarcoidosis, or the Besnier-Boeck-Schaumann disease, was estimated by Woods and Guyton[2] to constitute 2 to 3 percent of cases of endogenous uveitis. Longcope,[3, 4] Fisher[4, 5] and Michelson[6] have described the general features of the disease, and Walsh[7, 8] pointed out the relationship of sarcoidosis to Heerfordt's syndrome.

With the increasing recognition of sarcoidosis by clinicians in various fields, granulomatous uveitis and the other less common ocular manifestations are assuming a greater importance as links in the chain of diagnosis, and the severely damaged eyes, which may be almost the sole residual effect of the disease, pose a difficult problem to the ophthalmologist.

---

* Published with permission of the chief medical director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author. This group of patients was examined and followed as a part of a study of the effect of nitrogen mustard on sarcoidosis, which, with the approval of the National Research Council, was initiated by Dr. George E. Snider, and the preliminary report was made by him in January, 1948.[1]

† Resident in Ophthalmology, Veterans Administration Hospital, Fort Howard, Maryland.

The vitreous lesions consist of discrete grayish-white bodies occurring in the most dependent portion. They vary in size from dots to approximately one third of a normal disc diameter and are, for the most part, spherical. Frequently these bodies occur in chains like an isolated segment of a string of pearls. A few tubular forms have been noted, and occasionally other nondescript shapes. They may be seen with the ophthalmoscope focused on the retina, and focused in front of the retina up to a plus-10 reading. In all cases, they have been at least several disc diameters below the posterior pole, and are most numerous around the 6-o'clock position at the periphery. The bodies cast shadows from the ophthalmoscope light on the retina and the apparent distance of the bodies from their shadows indicates their relative position in the vitreous. It is almost impossible to see the lesions without fully dilating the pupil.

The patients studied were a group of 10 Negroes, two white men, and one American Indian. These veterans ranged in age from 21 to 35 years and all had generalized sarcoidosis including pulmonary lesions. All but one had peripheral node involvement. The various other sites included skin, lacrimal gland, epididymis, nasal mucosa, bone, and kidney. All diagnoses had been confirmed by one or more biopsies prior to examination by the ophthalmic department. Of the group of 13 patients, eight had eye involvement of some degree.

The three patients in whom the five eyes showed the vitreous lesions were young Negroes. All had chronic granulomatous uveitis characterized by greasy keratic precipitates on the posterior cornea, a positive aqueous flare, Koeppe and Busacca nodules, and a tendency to posterior synechia. The second eye of the third patient had a dense posterior synechia at the 6-o'clock position

which made it impossible to visualize the area in which the vitreous bodies might be expected.

The vitreous lesions have been observed only in the eyes of patients having relatively benign eye involvement. It is possible that the incidence of lesions in this group may be higher than has been indicated because, in the more severely involved eyes, it has been impossible to see the area in which they are to be found. Over a period of three months, there has been no marked change in the size, number, or character of the vitreous bodies in the five eyes, although in all cases the uveitis has become quiescent.

The present approach to the pathology of the vitreous lesions is necessarily indirect because all five eyes have useful vision. The area in which they are found suggests that they are of a higher specific gravity than the vitreous. The patient having the largest number of lesions was placed in a Trendelenburg position for three hours, and all patients were observed after periods of recumbency to check for drift of the bodies. However, no demonstrable change in their position was noted. It seems, therefore, that the specific gravity of the vitreous bodies must be essentially the same as that of the vitreous.

Two hypotheses as to the nature of these bodies have been considered; that they are similar in nature to Koeppe or Busacca nodules of the iris, which are collections of cells of the lymphoid series, and, that they are serous exudates which have been formed by an inflamed ciliary body and are therefore largely protein in composition. Up to the present, it has not been possible to prove or disprove either hypothesis.

Fig. 1 (Landers). The discrete, grayish white lesions were seen in the most dependent portion of the vitreous of a patient whose low-grade granulomatous uveitis was a manifestation of his generalized sarcoidosis.

It is possible that pathologic material may be available for the direct study of the vitreous lesions in sarcoidosis at a later date. In that event more tangible evidence will be brought to bear on this problem.

A COMPACT INSTRUMENT CASE*

JOHN W. WHOLIHAN, M.D.
Jackson, Michigan

Since ophthalmology requires so many instruments, the resident is at times puzzled as to what basic items he should have at hand to avoid omission of certain fundamental diagnostic steps.

The object of this article is to show that certain simple diagnostic instruments, drugs, treatment medication, and dressings can be readily carried in a small case. This instrument case is the outgrowth of several weeks of working with bulging pockets, frequent lapses in routine which necessitated revisits, and repeated trips to the supply room.

The convenience of the case is only one of its advantages. Besides making the taking of tensions a routine, unless contraindicated, it multiplied the number of interesting cases

seen. Several of the large wards at Wayne County General Hospital contain from 60 to 200 patients and frequently other residents, when on rounds, would ask for an
Fig. 2 (Wholihan). The case packed and ready to take on rounds.

* From the Wayne County General Hospital and Infirmary, Eloise, Michigan.

opinion or point out a case with unusual eye findings. The preliminary examination could be instituted on the spot rather than waiting until the resident had accumulated his "tools."

The photographs show the case which measures 9 by 6 by 3½ inches. The leather containers into which most of the smaller and less frequently used instruments fit are Schick razor cases. The contents of the case consist of:

1. Nine 0.5-oz., screw-top bottles containing frequently used diagnostic and therapeutic solutions.

2. Ophthalmoscope.

3. Tonometer.

4. Several visual acuity charts cut from a large chart and a near-vision, reduced Snellen chart.

5. A piece of exposed X-ray film, 5 by 15 cm. for screening.

6. Supply of sterile droppers.

7. Geneva lens measure, exophthalmometer, one-meter steel tape.

8. Several small instruments, epilation forceps, punctum dilator, syringe, and lacrimal canaliculus needle.

9. Condensing lens.

10. Roll of one-inch adhesive tape.

11. Supply of eye pads.

12. Supply of ointments.

13. Scissors.

14. Flashlight and extra batteries.

602 West Michigan Avenue.

EYE-DROP TRAYS

Max Kimbrig, M.D.
Huntington, New York

Errors caused by picking up the wrong eye-drop bottle, although rare, have occurred. One automatically checks himself several times before using any eye drops. This, and the fact that the bottle wanted is usually the last one picked up, means decreased office efficiency and annoyance.

The illustration shows an eye-drop tray which I designed and found to be an accurate and efficient aid in eye-drop selection. I made two identical trays for two treatment rooms. I am passing the idea along to anyone who is annoyed with time lost in searching for the right bottle; to anyone who wants to cut down the chances for error.

SPECIFICATIONS

Through a block of wood about 1 by 1½ by 11 inches, bore 10 holes, each ⅝ inch in diameter and about ⅜ inch apart. Glue a piece of cardboard on the bottom and set a ⅛ oz. dropper vial in each place.

A cellophane covered label in front of each hole matches the label on the vial, affording a double check on the vial's contents. This is really a triple check, for one can now reach for a bottle and know its contents by its location. The small vials can be filled from a stock bottle; or those seldom used, such as atropine, can be added to the vial in small quantities.

Effect of Procaine upon the Sphincter
Mechanism

Dr. Harold G. Scheie of Philadelphia discussed this topic. His remarks are here summarized.

Retrobulbar injection of procaine hydrochloride was found temporarily to produce the effect of a ciliary ganglionectomy. The pupil on the injected side, in animals and humans, dilated widely and became fixed. The effect persisted in dogs for 80 to 90 minutes and in humans for 1 to 5 hours. During that period of time, physostigmine was ineffective in producing miosis, but pilocarpine remained effective.

Pupils constricted by physostigmine prior to retrobulbar injection of procaine dilated promptly following retrobulbar injection but pupils constricted similarly by pilocarpine remained miotic.

Pilocarpine, therefore, should be the postoperative miotic agent of choice when prompt miosis is desirable following operations done with retrobulbar anesthesia such as a cataract extraction through a round pupil. Pilocarpine should likewise be used preoperatively when miosis is desirable throughout an operative procedure when done with retrobulbar anesthesia. A peripheral iridectomy, for example, is easier to do when operating for narrow-angle glaucoma if the pupil remains miotic.

Caution should also be taken to instill pilocarpine or a substance with a similar pharmacologic action into an eye prior to the use of retrobulbar injection of procaine hydrochloride for the treatment of acute congestive glaucoma. Failure to do so, or the use of drugs with an escrinelike action alone, would permit mydriasis and very probable aggravation of the glaucomatous state by further obstruction of the angle of the anterior chamber.

Studies were also done to determine the effect of procaine when applied locally to the iris. Prompt pupillary dilatation was obtained in dogs and cats from the injection of 0.1 cc. procaine into the anterior chamber. Pupillary dilatation of some degree was also obtained in human subjects following the instillations of two drops of 10-percent procaine in 1:3,000 phemerol at five-minute intervals. This mydriasis lasted for two hours. A mild cycloplegic effect was also observed.

Pupils dilated by the injection of procaine into the anterior chamber were resistant to all types of miotic agents even those which stimulate the muscle cell directly, such as calcium ions. It was therefore concluded that procaine probably exerts a direct depressant action upon the cells of the sphincter muscle when applied locally. Procaine should probably, therefore, not be used beneath the subconjunctival flap where prompt postoperative miosis is desirable or when miosis is desirable throughout an operative procedure.

Discussion. Dr. David Cogan asked what effect procaine has on the sympathetic ganglion, as far as the pupils are concerned.

Dr. Scheie replied that he had seen Horner's syndrome preceded by injection of the sympathetic ganglion, and that procaine would block a sympathetic ganglion much as it would any other nerve or ganglion.

Dr. Paul Chandler: This paper just reflects the ignorance of the rest of us in regard to this subject—the fact that we are unable to discuss it—and it points up what an original and interesting piece of work it is.

Dr. Perce DeLong, *chairman*

PLASMA CELL MYELOMA OF ORBIT

Dr. Joseph McEvoy (by invitation) said that tumors consisting of plasma cells occur quite frequently in the bone marrow and constitute one of the histologic types of multiple myeloma. Extramedullary plasma cell tumors, on the other hand, are of greater rarity.

A total of 128 cases of extramedullary plasma-cell tumors have been described in the literature. Most of these have been in the mucous membranes. The commonest site of occurrence is in the mucous membrane of the air passages and the next commonest site is in the conjunctiva, where 47 cases have been recorded. The only case involving the orbit that I have been able to find, other than the one described tonight, is the one described by Walsh, which he reports in his textbook on neuro-ophthalmology.

Histologically, the abundance of plasma cells is the outstanding feature of these tumors. The tumor cells are characterized by a large amount of cytoplasm and an eccentrically situated nucleus. The chromatin is arranged in cartwheel fashion, and a paranuclear unstained area is present. Cells with 2 or 3 or more nuclei are common. Other cells such as polymorphonuclears, lymphocytes, and histiocytes, if present at all, are never an essential part of the tumor.

When an isolated plasma-cell tumor is found, the question arises as to whether it is a solitary benign lesion, easily removed, or whether it is a part of the very malignant multiple myeloma. It seems that the microscopic appearance does not play an important role in predicting the clinical course of a given lesion. Even the appearance of mitotic figures in the cells does not indicate malig-

nancy. As long as the plasma-cell tumor is localized and confined to soft tissues and there is no other clinical evidence of multiple myeloma, cure can generally be obtained.

The case to be presented concerns an 80-year-old white woman who was admitted to the medical service of the Philadelphia General Hospital on May 26, 1948. She had no complaints, and was admitted simply for custodial care until admission to a nursing home could be arranged.

Physical examination revealed a well developed, but poorly nourished, anemic, old lady. The general physical examination revealed nothing of note other than the anemia which was hypochromic in type and thought to be nutritional. The right eye was blind. She had had a cataract extraction three years previously. The cornea was densely leukomatous. The left eye showed a senile cataract with vision of 6/60. There was a swelling of the right lower lid which felt like a firm mass extending into the orbit. This mass had been present about three months, was painless, and slowly progressing in size. There was no exophthalmos.

On June 16, 1948, surgery was performed under local anesthesia. The lower lid was incised along its entire length below the tarsus. Nothing was found in the lid itself. Within the septum orbitale was a reddish firm mass with a smooth, apparently encapsulated surface. By blunt dissection it was possible to separate the mass from the surrounding tissues, and follow it back into the orbit beneath the globe. It was shelled out, and removed in toto, measuring 3 by 1 by 1 cm. A large amount of hemorrhage was controlled with difficulty. A pressure dressing was applied. Postoperatively she developed a rather large hematoma of the operative site.

The pathologic report on this tumor is: The material consists of a homogeneous mass of uniformly dark, round cells—plasma cells. There is almost no stroma and practically no mitotic figures are seen. The diagnosis is plasma-cell myeloma.

X-ray examination of the skull, the orbit, the vertebras, the ribs, and the pelvis showed no evidence of bony myelomatous involvement. Repeated urinalyses showed no Bence-Jones protein. The serum calcium was 10 mg./100 cc. Examination of the sternal bone marrow showed no increase in cellularity and hematopoiesis was essentially normal. There was spotty infiltration throughout, with well-differentiated plasma cells.

The serum protein was 10.7 gm./100 cc. Of this 2.4 gm. were albumin and 8.3 gm., globulin.

This extreme hyperglobulinemia was thought to be highly suggestive of a diffuse myelomatous process in spite of the other negative findings.

The patient's right orbit was treated with two courses of irradiation of three doses each. The doses of X-ray therapy were 300 r., 600 r., and 900 r. at three-day intervals.

The postoperative hematoma completely absorbed in two weeks. No remaining tumor mass was discernible, and she was discharged from the hospital to a nursing home on August 24, 1948.

This case was presented as an example of an unusual orbital tumor and the difficulties of evaluation and prognosis of isolated plasma-cell tumors.

Discussion. Dr. Thomas Cowan: I have nothing to add as to the pathologic characteristics of this tumor, but the case does illustrate very well the difficulty of making a diagnosis before excision, and the desirability of excising so as to make a diagnosis. Clinically, the tumor impressed me as being benign by its appearance in the lid, and it had been so diagnosed elsewhere. As the orbit was entered, the characteristics of the tumor became more and more like those of a sarcoma. At its inner attachments it was so infiltrated among the tissues that it was very hard to remove surgically. Following the operation, the healing was very excellent for such an infiltrating tumor.

Dr. Perce DeLong: Plasmocytomas are not rare. However, few have been reported in the orbit.

The plasma cells are not easily recognized, because pathologically they present immature forms of the typical plasma cell, and for this reason are often referred to as myeloma cells.

The metabolic aspect of myelomatosis is interesting, in that it produces a protein in the urine which must be differentiated from albumin by the Bence-Jones test. If found, the diagnosis is quite conclusive. However, its presence is intermittent.

Dr. Joseph McEvoy: You mean the Bence-Jones protein test? Yes, we did it several times, and there was none found, but she did have an extremely high serum globulin.

ENDOTHELIAL MYELOMA (EWING'S TUMOR) OF ORBIT

CAPT. FRED HARBERT, (MC), U.S.N. (by invitation) AND COMMANDER GEORGE L. TABOR, JR., (MC), U.S.N. (by invitation) reported two cases of Ewing's tumor involving the orbit. The term Ewing's tumor is used to describe the clinical entity of a highly radiosensitive primary tumor of the bone which shows no true osteogenesis.

One of the cases presented was primary in the orbit with a rapidly fatal termination in spite of dramatic immediate improvement under radiation therapy. The other case was secondary in the orbit with complete replacement of osteolytic defects by normal cancellous bone following X-ray therapy.

The prognosis in a case of Ewing's tumor is considered to be inversely proportional to the degree of elaboration of recticulum. The histogenesis of Ewing's tumor and reticulum-cell sarcoma are considered to be identical.

Discussion. Dr. Perce DeLong: Ewing's tumors, by the majority of pathologists, are not considered a pathologic entity. It is a syndrome of a nonosteogenic, round-cell, radio-sensitive tumor, and this syndrome can be caused by many types of tumors.

The analysis of Ewing's tumors by many prominent pathologists showed that in a

majority of instances they were expressions of metastasis.

In the child and in the adolescent group, it was also found that they were not truly Ewing's tumors, but neuroblastomas, which proved to be metastatic, and finally, the ones that were primary proved in almost all instances to be reticulum sarcomas. If you notice, Dr. Harbert's second case was finally diagnosed as reticulum sarcoma. Ewing's tumor is not an entity, but a syndrome.

Dr. Fred Harbert: I must, of course, defer to your greater experience and judgment, but just from the standpoint of the clinician I think that Ewing's tumor is still a tenable diagnosis. What are you going to call the characteristic bony lesions when you cannot find a primary tumor, and throughout the subsequent course of the disease, you cannot ever find a primary soft tissue tumor? Ewing himself makes the absence of primary tumor a necessary criterion for diagnosis, so that at least it is a working diagnosis, and may have to remain even after postmortem. The differentiation between Ewing's tumor and reticulum-cell sarcoma is considered largely academic.

DIFFUSE INFILTRATION OF IRIS ASSOCIATED WITH NEVO-XANTHO-ENDOTHELIOMA

DR. GRACE R. NACHOD presented this paper which includes a brief discussion of the clinical and histologic picture of nevo-xantho-endothelioma together with a case report.

The case is that of a Negro male infant who was first seen because of a sore eye which proved to be due to a diffuse cellular infiltration of the iris and ciliary body with dislocation of the lens and secondary glaucoma. Shortly after the eye was enucleated, he developed multiple skin lesions, one of which was biopsied and diagnosed as nevo-xantho-endothelioma.

Although the cells that had infiltrated into the iris and ciliary body were somewhat similar to those seen in the skin lesion, no definite conclusions could be drawn as to their actual relationship.

Discussion. Dr. John Porter Scott: I speculate as to what would have happened had this eye not been removed. These lesions in the skin have the tendency to regress and disappear leaving no more scars than does chicken pox.

When I saw this child at the time the skin lesions first appeared, I thought that the eye had not been removed soon enough, because, in my ignorance, I assumed them to be metastatic lesions. At that time we had not received Dr. Fry's very excellent description of the tumor. Therefore, we were not sure just what the surgeon's diagnosis was.

Lesions of this type occur in some forms of storage disease. One of these is uncontrolled diabetes, in which xanthomatous lesions may appear. These are more yellow and less pink or salmon in color than the lesions in this child. As in this condition, they may disappear.

In Hand-Schüller-Christian's disease the lesions are yellowish, are larger, and have no tendency to disappear.

This case represents untrodden ground. I could not find any case in the literature in which the tumor was within the eye. One case was reported in which a tumor was in the orbit. I think the ophthalmologists should remember the appearance of this tumor. It would be extreme optimism to think that this tumor would have regressed as did the skin lesions. To repeat, I speculate as to what would have happened had the eye not been removed.

Dr. W. E. Fry: I think there are several features in regard to the eye specimen that might bear emphasis. The first is the infiltration of the iris which was very diffuse and very dense, and in which there were giant cells of the Touton giant-cell type similar in appearance to the Touton giant cells that appeared in the skin lesion, and which I understand are important for the diagnosis of the skin lesion. The eye had been

fixed and dehydrated in ether and alcohol so it was not possible to carry out fat stains. These would have been useful. Fat stains on the skin specimen showed a marked degree of fat.

The other feature that was important was the anterior dialysis of the retina through which apparently the dislocated lens had slipped. Just how this had occurred is entirely speculative. One possibility is that the lens dislocation could have been produced artificially when the eye was cut previous to embedding. This is unlikely, because, of hundreds of eyes that we do cut, if they are cut with reasonable care, no dislocation of the lens occurs, and if it does occur it is not dislocated behind the retina. The secondary glaucoma, probably caused by the dislocated lens behind the anterior dialysis, could have led to severe changes in the eye so that enucleation was indicated.

The question comes up as to whether these lesions in the iris regress. Probably they do, and this is probably why we have not seen them or they have not been reported to any extent before. In all probability, if the glaucoma changes had not occurred the eye might have cleared up, and the lesions regressed spontaneously.

Dr. Herman Beerman: I know the history of this patient and the pathologic findings very well, because I had the opportunity to study the cutaneous specimen, and Dr. Fry was good enough to allow me to study the eye slide. Although Dr. Blank, Dr. Eglick, and I have reported this case from the pediatric-cutaneous standpoints, I hope we have not interfered with Dr. Nachod's plans for publication of the ocular findings.

This is an extraordinarily rare case, and, as was previously mentioned, there is only one other instance in the literature in which eye complications have been noted. This was a patient reported in the discussion of Dr. Lamb and Dr. Lain's paper by Dr. Ellis of Baltimore. No further details are available on this case. Therefore, the present case is unique. I believe it is the first authentic

instance in which both cutaneous and ocular complications have occurred, and in which their identity was proved by pathologic examination.

I believe, in retrospect, that when one visualizes the amount of ocular damage present one cannot say the eye lesion would have regressed without necessitating enucleation. I do not believe, therefore, that anyone who handled this patient need fear criticism for the procedure employed.

Dr. A. G. Fewell: I thought the eye should come out, as the whole iris seemed to be thickened and infiltrated with the growth. The tension was rather high, and the eye was apparently blind.

Dr. Grace R. Nachod (closing): I am grateful to Dr. Fry and Dr. Fewell and Dr. Beerman for mentioning the fact that they thought the enucleation was indicated. I wondered about it a little bit myself; and am grateful to Dr. Scott for his discussion.

GENERAL ANESTHESIA IN OPHTHALMOLOGY

Dr. H. H. Stone (by invitation) read a paper on this subject.

Discussion. Dr. Edmund B. Spaeth: Some time ago, while discussing anesthesia for ophthalmic surgery with an anesthetist, not Dr. Stone, this statement was made by that anesthetist, "I do not understand the tremendous differences of opinion relative to general anesthesia which one observes when talking with different ophthalmic surgeons; I doubt whether there is anything more chaotic in surgery than that."

This observation has been made by other men. The fault, or perhaps the reason, for that state of affairs is not strange. There are three factors responsible. The ophthalmologist is only concerned with one of them, namely, his willingness to consider each case for surgery as an individual problem, and in each case whether the surgery indicated can best be done on the patient under consideration with local or general anesthesia.

The second factor is the brief, but rather essential, physical examination by an at-

tending internist, and the consideration of his recommendations as to which kind of anesthesia is to be used.

The third factor is the anesthetist's problem. Which type of anesthesia is to be used, inhalation anesthesia, intravenous anesthesia, or rectal anesthesia? All have optimum indications for use; each handles best a group of situations present. It is seldom, in recent years, that we suggest the type of general anesthesia to be used. Our wishes should be considered as to whether the surgery should be done under local or general anesthesia; but the anesthetist and the internist are responsible for the type of anesthesia to be used on each patient.

There is no doubt whatsoever but that the increase in the use of general anesthesia is directly proportional to the efficiency and the understanding of ophthalmic surgical problems by the anesthetist. We feel unusually fortunate to have Dr. Stone for our surgical cases.

Because of his efficiency and his department, we now view anesthesia quite differently. In the past, general anesthesia was used only when absolutely necessary. At the present time it has become the choice in many surgical procedures. Intraocular operations are still to be done under local anesthesia if possible; on the other hand, one need no longer dread them under general anesthesia, nor need one fear postanesthetic accidents and complications. This is quite a reversal in practice.

Plastic surgery, even the relatively minor procedures, can be done so much better without infiltration and/or block anesthesia otherwise necessary. Lacrimal-sac surgery, with its rather exacting anatomic dissections, is definitely simpler when performed under general anesthesia.

All types of muscle surgery, regardless of the age of the patient, are shortened in operating time and simplified without injections into the capsule sheaths which are necessary to make that surgery painless. Surgery for retinal separation, which can vary from a relatively brief period of operating time to hours on the operating table, when done under general anesthesia is far less taxing to the patient, and very much easier for the surgeon.

These procedures need little if any change in essential techniques regardless of the type of anesthetic which is used. Intraocular surgery, when done under general anesthesia, must have certain rather important changes in the surgical technique, connected with fixation of the globe and the support of the lids. This is outstanding with corneal grafts; in fact, it is so important with this latter type of surgery that it is used also at the first dressing of the patient's eye.

In the final analysis, a paper such as Dr. Stone has just given us has greater significance to anesthesiology than to ophthalmology. The anesthetist cannot take care of ophthalmic cases unless we are willing to permit it, and to coöperate with him at the same time. General anesthesia should play a bigger role in ophthalmic surgery than it does, considering, naturally, the availability of trained medical specialists in anesthesiology.

Dr. H. H. Stone (closing): Up to the present time we have had no fatalities. We occasionally do get into difficulty, and I think you get into difficulty no matter what type of anesthesia you use. We have seen difficulty with local anesthesia. Not especially in eye surgery, but we have had two fatalities when general surgeons were using local anesthesia. The expert should give the anesthetic for ophthalmic surgery.

I feel there is not a more difficult case than the cataract extraction under general anesthesia, not barring chest surgery. It takes far greater skill to keep these patients breathing yet not coughing or sneezing when the cataract is removed, and keep them well oxygenated throughout the entire procedure, than is required for a 5 or 6 hour pneumonectomy.

M. Luther Kauffman,
Clerk.

CHICAGO OPHTHALMOLOGICAL SOCIETY

December 20, 1948

DR. A. C. KRAUSE, *president*

CLINICAL MEETING

Presented by the Department of Ophthalmology, Northwestern University Medical School.

CONVERGENCE INSUFFICIENCY

DR. BRUCE MCCLELLAN presented a 37-year-old man who was first seen at the eye clinic about one month ago, with a complaint of headache associated with eyestrain and a "drawing sensation" about the right eye. His eyes have turned out since he was a child, but medical advice had not been sought until the symptoms became worse.

Examination showed 20/20 vision in each eye; refraction showed a +0.75D. sph. with a small cylinder for each eye. On the screen test for distance he measured 45 prism diopters divergence for distance and 65 for near, with a left heterotropia of 4 diopters for distance and 2 for near; these measurements have been repeated on three successive tests. His near point is remote; however, this is not a true case of heterotropia because he can fuse; he can fuse for near, the near point being forced to 110 mm. on the first examination, and, on the second, to 90 mm. with the right eye deviated. He prefers the left eye for distance and for near. There is marked underaction of both superior recti muscles, the right more so than the left; also underaction of the medial rectus muscles.

The diagnosis in this case was convergence insufficiency, secondary to divergence excess, also bilateral superior rectus paresis with overaction of both inferior oblique muscles.

Discussion. Dr. Beulah Cushman felt that the convergence insufficiency is secondary to the divergence excess, which always becomes a complication sooner or later. It becomes apparent as the accommodative power is reduced. This patient at the age of 37 years is having difficulty maintaining single vision for near work; the divergence for distance has been present since youth. The vertical anomaly is the primary factor. Surgery will include first the correction of the convergence insufficiency with resection of the medials and recession of the overactive oblique; at the second step there will be recession of the laterals.

Dr. E. H. Merz said the surgery mentioned will correct the vertical anomaly and the horizontal can be corrected at a later date. As Weidman states, most horizontal errors are secondary to vertical abnormality. It has been reported that these conditions can be corrected with tenotomies of the inferior oblique or recessions.

Dr. Kirby and Dr. White have commented on conditions where complete tenotomy has resulted in complete paralysis of the inferior oblique. If there is complete paralysis of the inferior oblique and of the superior rectus, there is a posterior head tilt which is undesirable.

Dr. Scobee has reported a case of bilateral paralysis following surgery in which pseudoptosis resulted because of the marked back tilt of the head. The congenital paresis is due to an error in cleavage of the common premuscle mass. These conditions are not uncommon. White, Kirby, and Dunnington say they are the most common of all muscle conditions. The superior rectus muscle differentiates from the group later than any other, and for that reason more congenital anomalies are found in that muscle.

FRACTURE OF FRONTAL BONE

DR. PAUL R. IRVINE reported a 10-year-old girl with a history of a fall from a bicycle. Whether she suffered a concussion is not clear; she was said to have struck the right side of the head on the handlebar or a rock. At the time, nothing was noted except slight discoloration at the right outer canthus. Approximately one hour after the accident some

swelling was noted about the eye. This became more marked and, 48 hours later, she was seen by an oculist. On the suggestion that a hematoma was present a conjunctival incision was made but no blood drainage resulted. About five days later nausea and dizziness occurred and she was put to bed, without improvement.

Ten days ago she was first seen at Passavant Memorial Hospital. On examination the right eye was proptosed and depressed. Vision was: R.E., 20/200; L.E., 20/20. Palpation over the lacrimal gland revealed a mass which was thought to be a dislocated lacrimal gland; a smaller mass was noted nasalward. X-ray films showed fracture of the frontal bone extending into the roof of the orbit. Neurologic consultation advised conservative management; they felt there was not only a hematoma but a cerebrospinal leak. On dismissal she had no diplopia.

Discussion. Dr. Derrick Vail said that this case emphasizes that one should not be too hasty in entering an orbit for acute proptosis even with the practical certainty that it is due to subperiosteal hematoma from injury. It is not unusual to find reports in the literature of acute proptosis due to hemorrhagic extravasation under the periosteum in patients who had scurvy, particularly infants.

When the X-ray films in this case were received from the family doctor, surgery was scheduled. As a precaution, however, further X-ray studies were made which showed the fracture and the operation was therefore cancelled. The fracture, as shown on the slides, extended into the roof of the orbit. The family doctor had mentioned that, on inserting a needle, he had withdrawn about 0.5 cc. of clear fluid; that report should have led to the suspicion of a leak through the roof of the orbit of cerebrospinal fluid. It is, however, not unusual to obtain some fluid from the orbit on diagnostic puncture in cases of acute proptosis; fluid from edema, for example, can be drawn into the syringe.

Certainly, in this case, conservative treatment was well worthwhile. The neurosurgeon feels that the crack will heal fairly well and if, at the end of six weeks or so, there still remains definite proptosis, particularly if a swelling is palpated in the roof of the orbit, a small incision to see if there is an encapsulated hematoma is probably justified.

PROGRESSIVE MENINGIOMA

DR. R. D. TEBBETT presented two cases. The first was that of a 54-year-old white woman who complained of gradually increasing weight for 17 years, blindness of the left eye for 10 years, and failing vision in the right eye for one year. In 1931, she weighed 131 pounds and at present she weighs 245. In 1940, she got something in the right eye and as she rubbed it she noted that the left eye was completely blind. Apparently the cause for the loss of vision was primary optic atrophy, but the cause was not determined. She was told that the right eye would probably never be affected. In January, 1948, she noted decreasing vision in the right eye, with what she described as a gray area in the lateral part of the field. Glasses were prescribed which improved the vision somewhat.

When she entered the hospital in July, 1948, vision in the right eye was 20/70. The left eye showed a cataract and primary optic atrophy. The right disc was pale; the scotoma descended from above laterally to the fixation point. Neurologic examination was essentially negative; spinal fluid was normal. X-ray studies of the skull showed proliferative changes of the inner table of the frontal bone and the rostral and dorsal portion of the sphenoid. It was decided that she had a meningioma which had probably been progressive for 10 years or more. Surgery was not advised.

TUMOR OF ORBIT

The second patient, presented by Dr. Tebbett, was a 33-year-old white woman who had had proptosis of the left eye, apparently of mild degree, for 3 or 4 years. Ten days prior

to entry she noted increase in the proptosis; in fact, the eye herniated between the lids. She entered the hospital for observation, and a lateral tarsorrhaphy was done to prevent further herniation of the eye. Previous X-ray studies were reported as negative.

Eye examination was essentially negative with the exception of the proptosis which measured: R.E., 13 mm., L.E., 27 mm. The eye was proptosed directly forward without lateral displacement. Visual fields were normal. Neurologic consultation was essentially negative. There was no bruit over the proptosed eye. There was a question of frontal-lobe disturbance because of the slightly disturbed judgment of the patient during questioning. X-ray films at this time showed marked erosion of the optic foramen on the left side, erosion of the lesser wing of the sphenoid, and erosion of the greater wing of the sphenoid.

Operation was performed by the neurosurgical service and a dumbell-shaped tumor was found, the greater part of the mass lying in the middle fossa extending up through the left optic foramen and into the orbit. The entire multiloculated tumor was removed at the time of operation. The pathologic report is, as yet, debatable. It has been reported as a neuroma and also as a meningioma.

Discussion. Dr. Derrick Vail felt that these two patients were most instructive for demonstration because they emphasize so clearly the point that one cannot ignore optic atrophy or dismiss it lightly without being satisfied that every possible avenue of investigation has been exhausted—even then it should be considered as an unsolved crime, which should cause concern to the ophthalmologist. If the first patient had had the proper diagnosis, early surgery could probably have been done. After 10 years of obesity, increased blood pressure, cardiac and arteriosclerotic changes she was not a suitable neurologic risk.

This woman's youngest child is about 8 years old and she feels, as does the surgeon,

that it probably would be best, with a slowly-developing malignant tumor—not malignant in the sense of metastasis but in destroying the adjacent tissues—to go on, with the possibility of keeping a small degree of sight, gradually getting worse, but at least keeping her life during the next few critical years of bringing up this child. She knows the whole story, has the utmost courage, and has faced the issue most cheerfully. Had surgery been attempted the neurosurgeon felt that a fatal result was pretty certain.

The second case is an example of the same situation. The patient had proptosis for 10 years, gradually getting worse, and more or less ignored the condition. Five years ago she consulted an ophthalmologist who found some proptosis, but the X-ray report was negative and he felt that there was no particular reason to account for the proptosis. An interesting feature of this case is that the proptosis is directly forward, which would indicate disturbance in the muscle cone; also that the vision is entirely normal in each eye and, third, that the optic nerveheads were entirely normal; the fields of vision were entirely normal; and there was no interference with ocular movements and no diplopia.

The situation became critical when she had sudden herniation of the eye, a catching of the upper lid behind the proptosed eye, which alarmed her considerably and she sought help. The X-ray film shows a striking phenomenon; complete erosion of the entire outer wall of the optic foramen. To take a picture of the optic foramen requires special technique and the X-ray man must be instructed to get a good view of the optic foramen. Extensive erosion of the sphenoid wings is also shown. Not many conditions produce such a picture—proptosis with erosion of the optic foramen and sphenoid wings.

The first thing to be considered is meningioma, and meningiomas are not unusual in females particularly. The second thing is

aneurysm, but there was no suggestive history and aneurysm would have undoubtedly interfered with some of the ocular movements. In view of the experience of Dandy, Cushing, and Eisenhardt—whose monograph is one of the classics of ophthalmic literature —it was felt that to perform an orbital operation in this case would be a mistake, and that the transfrontal approach was necessary.

Almost all cases are not purely local in the orbit, but secondary, by extension through the apex of the orbit from a meningioma arising usually on the lesser wing of the sphenoid. To give the patient every chance possible, the transfrontal approach must be used because, if there is proptosis plus bone changes, it is evident that an intracranial tumor extending into the orbit is present. To do an orbital exenteration only is but half the job; whereas, by transfrontal approach the neurosurgeon skilled in his work can unroof the roof of the orbit and find the tumor, as was done beautifully in this case.

It is a mistake, therefore, for the ophthalmologist to carry out orbital exploration, particularly in view of the possibility of meningioma. It is gratifying to report that this woman is recovering well, the proptosis has entirely receded and it is now just a matter of complete convalescence to be followed later by opening the lids.

These two cases should, therefore, emphasize that one should not be content with a purely objective diagnosis of optic atrophy, but should seek the cause, and should not be satisfied until that cause is found.

Dr. James E. Lebensohn: The first case, in which there was optic atrophy in one eye and central scotoma with expansion temporally, is probably one phase of the Foster-Kennedy syndrome; in fact, the Foster-Kennedy syndrome is more often found with suprasellar meningiomas than with frontal-lobe tumors.

The development of field changes is interesting. Pressure produces primarily a central scotoma which expands centrifugally, hence

producing first a temporal pallor and then the picture of primary optic atrophy. On the other hand, the papilledema on the contralateral side shows primary loss in the peripheral field, continues with centripetal contraction until finally secondary optic atrophy results. Among the significant findings that distinguish secondary optic atrophy of this type are occasionally concentric rings around the optic disc.

Pituitary adenoma is only one of the possible causes of bitemporal hemianopia. Similar effects on the chiasm may be produced by meningiomas, glioma of the chiasm, aneurysm of the anterior cerebral artery or its communicating branches, and chiasmal arachnoiditis. Careful study should indicate the differential diagnosis in any particular case.

SCIENTIFIC PROGRAM

PRIMARY LIPID DYSTROPHY OF THE CORNEA

DR. DANIEL SNYDACKER presented the case of a Negress, aged 20 years, with an unusual bilateral, symmetrical, ring-shaped corneal opacity. The appearance of the lesion, the lack of a demonstrable etiology, and the presence of an elevated blood cholesterol pointed to the diagnosis of a primary lipid dystrophy of the cornea.

Discussion. Dr. J. V. Cassady mentioned a similar case which he had had under observation. The patient was a 56-year-old woman who had a central type of xanthomatosis of the cornea rather than the peripheral type presented by Dr. Snydacker. There was a deep, central, yellow, vascularized corneal opacity in one eye, which had gradually developed without antecedent trauma or inflammation. Occasionally it was irritated and red, but usually without subjective symptoms other than blurred vision. Katz and Delaney described a similar central lesion in lipid dystrophy of the cornea. Dr. Robert von der Heydt confirmed the diagnosis in this case. The Wassermann and Mantoux tests were negative; the patient had 225 mg. blood

cholesterol, hypercholesterinemia. Vision in the other eye was normal, although many cases are bilateral.

Dr. Peter C. Kronfeld had observed for some time a patient whose eyes are similar to those of Dr. Snydacker's patient. Little was known of the history in this case. Her two sisters were blind from a gross form of this dystrophy and, while he had not seen them, they had been described by an eye doctor in their home town, and the corneas were completely opaque. In the two sisters, the disease took the same course as in the woman under observation. All have marked hypothyroidism and all are much overweight, none weighing less than 220 pounds. The symptoms started during the third decade of life. The patient under observation still has 20/20 vision in each eye. She has been put on a diet of 1,000 calories a day, plus vitamins. Her blood cholesterol is high, and the determination on one of the sisters was also high.

Dr. Robert W. Zeller said that, after a previous admission at Cook County Hospital in 1946, this patient again came under observation in 1948. In 1946 there was a flareup of the keratitis following injection of tuberculin; it was felt that the keratitis might have been on an acid-fast basis. She was not seen for two years when she returned because of a fractured vertebra.

The basal metabolic rate was then −23; subsequent determination were −17 and −9. The first determination was probably the most significant of the three. Total cholesterol was 186 mg., within normal limits. Total protein determination was 7.6, albumin was 4.2, and globulin, 3.4, which is rather high. The cephalin flocculation was 1+ positive. Thymol determination was 7.4 units; the upper limits of normal at County Hospital Laboratory is 5 units.

The biochemist felt that these determinations indicated possible minimal liver damage; he also said that the thymol determination had to do with determination of lipids

in the blood and, if elevated, might substantiate the diagnosis of lipid dystrophy.

This case was seen by Professor Van Ness who was here from Finland. He has apparently had a case of true lipid dystrophy, one of the seven reported. He felt that this was a case of lipid dystrophy also. It might be worth while to use choline in this patient, following Dimitry's suggestion. It is known to be a fat solvent, and might possibly bring about dissolution of the opacities.

Dr. Daniel Snydacker (closing): In answer to Dr. Zeller's question about the use of choline, it is doubtful if this would be of value because the opacities are deep and the choline probably could not reach them, and the basis of the treatment involves actual contact.

CHOICE OF OPERATION IN ACUTE GLAUCOMA SECONDARY TO SWELLING OF THE LENS

DR. PAUL STERNBERG AND DR. SAMUEL J. MEYER presented a paper on this subject and discussed choice of operation for an eye in which glaucoma is secondary to lenticular intumescence. It is believed that the acute, congestive glaucomatous attack which is said to be secondary to lens swelling occurs in an eye that may be termed preglaucomatous. The opposite eye is frequently of the preglaucomatous description, with a narrow entrance to the angle of the anterior chamber.

An iridectomy, if done early, or, if done later, an iridencleisis are the operative choices for reducing the increased intraocular pressure. An intracapsular cataract extraction is performed subsequently with use of corneoscleral sutures.

Discussion. Dr. Derrick Vail agreed with Dr. Sternberg that, in one's experience, glaucoma due to an intumescent cataractous lens will be encountered sooner or later. The essayists have given clear indications for various types of surgery in this condition, but he differed on some of the points expressed.

The glaucoma is due entirely to the swol-

len lens; that is a mechanical fact. Whether or not the angle is narrow prior to development of the intumescent lens is not pertinent to this discussion, because in any cataract case, if the lens is allowed to remain and become intumescent, there will be a rise in intraocular pressure at some time or other.

This occurs when the swelling of the lens reaches its maximum and may not precipitate an acute attack, but will result in a period of increased intraocular pressure followed in time by decrease in pressure as the intumescence recedes.

A mature cataract undergoes a varying process of evolution, eventually leading to the morgagnian type where the nucleus falls to the floor. If the morgagnian cataract is permitted to remain, the milky lens material eventually absorbs if it does not leak out through a spontaneous rupture of the anterior or posterior capsule, in which case there is bound to be considerable difficulty in the eye with iridocyclitis and secondary glaucoma. If the capsule remains intact the milky substance generally absorbs, leaving the condition that has been described in the literature: a shrivelled nucleus held between two collapsed capsules; in which case, of course, the glaucoma is not a problem because, if it did exist, it had spontaneously taken care of itself.

The point about the narrow angle as a provocative condition deserves considerable emphasis. It certainly should make one more careful in the study of these cases, particularly so far as the opposite eye is concerned. In ordinary acute glaucoma due to an intumescent lens, the lens should be removed as the primary cause of the glaucoma. In the literature there are described the use of pilocarpine and preliminary operations such as iridectomy and iridencleisis, which are apparently not necessary; in an experience with 10 or more such cases, the cataract has been removed successfully even in the presence of high intraocular pressure and a congested eye. The lens may be removed in

its capsule by the Smith method and, on the second or third day following, the eye is white and obviously grateful for the surgical interference. As Colonel Smith has said, the lens in such cases may be dislocated almost by "an angry look." To try to deliver the lens with capsule forceps is almost futile, because it is like trying to pick up a piece of soap in the bathtub.

A procedure recently advised by Dr. Daily is to prick the capsule with a small needle, letting out some of the material which, in turn, reduces the intumescence and permits grasping the capsule with forceps. Another method described is to open the capsule with a diathermy coagulation needle as a preliminary step. That seems rather involved when a needle will serve the purpose. Some men have had success with the erisophake, but in his own hands the Smith operation for this type of case is ideal.

An illustrative case is one of a patient operated on, in 1915, by Dr. Derrick T. Vail, Sr., at which time a cataract was removed from the right eye. The patient was satisfied with the result, he saw well, and was advised to have the lens removed from the other eye, which advice he ignored and went on for 10 years; the lens, of course, becoming more and more mature.

When seen at that time the lens was becoming hypermature and removal of the cataract was again advised. Six or eight months later he came in with an acute attack of glaucoma. He was almost 80 years old, had a vascular hypertension of 200+, he had had a coronary attack about two years before, he had nephritis, and could not possibly have been a worse risk.

However, although the problem was approached with fear and trembling, the incision was made ab externa, as so ably described by Dr. Meyer, the incision was enlarged with scissors, sutures were placed, and an iridectomy was done.

In doing the iridectomy the lens came forward and it was just a matter of touching

it gently through the cornea to deliver it by the Smith method. Surprisingly, an expulsive hemorrhage did not occur and the eye turned out very well indeed; the second day following operation it was as white as in the ordinary case and the patient made a complete recovery without any complications whatsoever. Thus, in certain conditions, one is justified in performing an intracapsular operation even in the presence of a high degree of glaucoma.

{ Possibly one reason why iridectomy has failed in these cases is because anterior peripheral synechias have developed, as pointed out by the essayists. It is not certain that an iridencleisis in these cases is advisable, because the angle is already blocked by the intumescent lens, and although the essayists have demonstrated that this is a theoretic objection, it is conceivable that one will temporize and delay and lose valuable time in permitting filtration to function. Such an eye is subjected to two procedures rather than one. *{|*

INTRAORBITAL ANEURYSM

DR. ROBERT F. HEIMBURGER (by invitation), DR. H. ROBERT OBERHILL (by invitation), DR. H. ISABELLE MCGARRY, AND DR. PAUL C. BUCY (by invitation) presented a paper on this subject and reported a case of exophthalmos due to aneurysm of the lacrimal artery contained entirely within the orbit. Transcranial exploration of the orbit and removal of the aneurysm of the lacrimal artery resulted in the patient's recovery.

A survey of the literature shows no other verified case of aneurysm of the lacrimal artery and, consequently, the criteria for differential diagnosis cannot be set up. Unilateral exophthalmos without pulsation but with evidence of venous obstruction, increased intraocular pressure, and failing vision were the clinical manifestations of the case presented.

Discussion. Dr. Paul Bucy was surprised to find that these are such uncommon lesions and that even those cases so listed in the literature are practically all questionable. In view of that fact it is even more remarkable that Dr. Kronfeld made the correct diagnosis preoperatively. This is an interesting problem, one which can be best dealt with if the lesion is in full view, as is possible with a transfrontal operation.

Dr. Peter C. Kronfeld recalled that when this patient was first seen she had progressive exophthalmos, ocular hypertension refractory to everything that was tried, limitation of ocular motion, swelling of the disc, and retinal hemorrhages. By this neurosurgical operation she has been cured. The present function of the eye is normal. One thing that was perhaps omitted was a more thorough study of the ocular hypertension. It apparently was a case of hypertension due to interference with venous outflow; somehow the aneurysm interfered with outflow of one or both ophthalmic veins; it would have been interesting to study this more in detail. It looked alarming and since it was felt that it was probably an aneurysm, the patient was referred to the neurosurgeon. In watching the operation, it is apparent that there is no possibility of exposing such a lesion equally satisfactorily through the anterior aperture of the orbit. While the great advantages of the transfrontal, transcranial approach to the orbit have been appreciated, this particular case is convincing proof that many cases of orbital tumor deserve the transcranial approach.

Richard C. Gamble,
Secretary.

AMERICAN JOURNAL OF OPHTHALMOLOGY

Published Monthly by the Ophthalmic Publishing Company

EPILOGUE

Flying 25,000 feet above the Atlantic ocean; behind, two weeks of American hospitality; in front, the old routine of work; it seems a good moment—the first opportunity in two weeks to sit back and relax—to send American ophthalmology a "thank you."

These two weeks have indeed been full to overflowing—one at the academy meeting at Chicago, a week-end at St. Louis with the local ophthalmological society and the American Board of Ophthalmology, followed by a week with the American College of Surgeons again at Chicago—two weeks of scientific papers and exhibitions, of social and academic functions, a whirl of events guided with what appears to be effortless efficiency, from companionable breakfasts through the crowded sequence of the day to the boundless hospitality of the evening and the good fellowship of the early morning.

This was the first academy meeting I have attended. I have taken part in many meetings in many countries; but there has been none like this. My main impressions were of the vastness of the meeting and the ordered rush of 4,000 members (all so enthusiastic)

and almost 4,000 wives (all so delightful); the immense caravanserai of a hotel that absorbed them into its interstices like a hydrophilic gel, apparently without effort or disturbance of its normal routine; the crowd of events that can be fitted into a day; the excellence and variety of the scientific program; the amount and the modernity of the scientific equipment on exhibition; and finally, and by no means least, the value and comprehensiveness of the courses of instruction—a feature unique to the academy which must be of immense educational value to the more isolated practitioner, whereby each year he can refresh himself in fundamental procedures and acquaint himself with recent advances at the hands of acknowledged authorities. But the most pleasant time of each day was the hour before dinner when everyone "visited" and I met intimately the many friends who have now become an accepted part of my life.

Without doubt the academy is one of the most important influences in American ophthalmology. The atmosphere of the meeting with its nice balance between professional and social activities, between what is new (as seen in the papers presented) and what is established in ophthalmology (as seen in the instruction courses), is an immense stimulus to the visitor and must be an equal stimulus to those practicing in a country wherein distances are measured in thousands of miles; but one hopes that it will not become much bigger and busier lest it topple over by its own weight or explode. So far as the present meeting was concerned, the burden thrown upon its organizers must be immense, but it is a burden that they can obviously carry and it was a pleasure to witness the effortless ease with which Conrad Berens presided over it, aided immensely by the charm of his wife.

The American College of Surgeons formed a second week of equal interest, but with 5,000 delegates instead of 4,000—the same high standard and breadth of scientific proceedings and the same good fellowship.

The highlight of this meeting was the colored television—a thousand people at a time could follow in its detail an operation for cataract carried out, with a running commentary by the surgeon, in a hospital in another part of the city. In this meeting, however, ophthalmology occupied a small corner. Is that wise? If ophthalmology stands alone outside the umbrella of general medicine and surgery, it will lose much of its inspiration and philosophy.

In both these meetings the outstanding impression carried away by the European visitor is their vastness. For example, at the convocation of the college almost 1,000 candidates were initiated into the fellowship at one time. This is the greatest difference between America and Europe. In Europe the standards are as high and the men as good; but the mass and weight of America must give it an immensely preponderating influence in world medicine. With this comes responsibility—a responsibility which America must accept, and is indeed accepting with enthusiasm and confidence.

Stewart Duke-Elder.

PIGMENTED TUMORS

The beautiful exhibit of Dr. Arnold Zimmerman at Atlantic City which displayed the results of the work of an anatomist on a dermatologic problem is of the greatest interest to ophthalmologists. His preparations showed clearly that the pigmentation of the skin does not arise by synthesis of melanin in the epithelial cell. Instead it is elaborated in specialized branched cells called melanophores which invade the embryo skin from afar and transfer their melanin to epithelial cells.

It seems not unreasonable to speculate that the cells of the choroid also receive their pigment from specialized pigment-bearing cells if, indeed, the melanophores of this membrane are not actually similar cells that have originated in the embryonic neural crest. If this is true, then the tumor known

clinically as sarcoma of the choroid is actually a neurogenic tumor.

A dozen years ago Georgiana Dvorak-Theobold (Tr. Am. Ophth. Soc., 1937) thoroughly reviewed the subject and suggested that the most tenable hypothesis is that of Masson in whose opinion the cells of these tumors, as well as of nevi, are derivatives of the cells of the sheath of Schwann. There still is doubt about the origin of the cell. Recent studies of the origin of melanoblasts, or cells that elaborate melanin, are most suggestive and may point the way to a solution of the complex problem.

There is of course no conclusive evidence that the origin of the pigment-bearing cells of the choroid have the same origin as the melanophores elsewhere in the body but it is at least probable that this is true. It has long been accepted by zoologists that the pigment-producing cells of amphibia and birds arise from the embryonic neural crest. The melanoblasts of mammals were thought to have a different origin.

The recent experimental work of Mary E. Rawles (Physiol. Zoöl., 20:248, 1947; Physiol. Rev., 28:383, 1948), however, supports the view that this is not true. She tested the potency of various portions of mouse embryos of a homozygous black strain ranging in age from 8 to 12 days' gestation by isolation and transplantation into the celom of white-leghorn chick embryos of 60 to 65 hours' incubation. In this site the transplants were allowed to grow until the host hatched. Isolations were made at various axial levels of the embryo in such a way as to test tissues of the central nervous system, adjacent tissues of the somite, and lateral plate and limb-bud regions for pigment-cell production in the grafts.

It was clearly shown that melanophores can be produced only from tissues that contain presumptive neural crest, histologically recognizable neural crest, or cells in migration from the neural crest. Skin and hairs that were completely normal except for the absence of pigment and pigment cells grew in all the grafts whenever neural crest had been excluded.

The development of structurally normal white hairs from a potentially pigmented mouse is conclusive proof that the formation of melanin pigment in the ectoderm and its derivative, the hair, is entirely dependent on one particular type of branched pigment-forming cell, the melanophore, which originates in the neural crest. Several hundred grafts were made.

That epithelial pigment in man also arises in neural melanoblasts was shown by Zimmerman and Cornbleet (J. Invest. Dermat., 11:383, 1948) who studied the development of epidermal pigmentation in the Negro fetus. Specimens of skin were taken from the scapular and abdominal region of 50 fetuses obtained by abortion.

Dendritic melanoblasts, with incompletely elaborated melanin, appear in the third month and from their first appearance do not resemble epithelial cells. They give a faintly positive dopa reaction which indicates that they elaborate an oxidase that is essential to the synthesis of the melanin, and epithelial cells do not. The melanoblasts progressively pervade the epidermis through the intercellular spaces and form an intricate pattern by their long processes. The epithelial cells acquire melanin secondarily by transfer from the dendritic processes of the melanoblasts.

Carcinomas that arise from the pigmented basal layer of the skin are only moderately malignant; whereas, the melanoblastic neoplasm is wildly malignant. The latter has a tendency to spread in sheets along preformed surfaces. The sheath cells, which are thought to be the cell from which choroidal sarcoma originates, are indeed sister cells of the melanoblasts but they give rise to sarcomas that are sparsely pigmented, if at all.

It is also interesting to note that workers in diverse areas of thought are uncovering interesting related data on the origin of pigment cells and that their findings all sup-

plement and support each other without essential reservation.

That this is true justifies the belief that in time the work now in progress will also clarify the specifically ophthalmic problem of pigmented tumors.

F. H. Haessler.

TRAINING IN OPHTHALMOLOGY

The American Board of Ophthalmology examinations afford an excellent opportunity to evaluate the present-day training available for men wishing to enter ophthalmology. Here it is possible to compare the knowledge acquired by the candidate in the various training facilities.

In certain circles there is the opinion that unless a man has had a regular residency in one of our better-known training centers there is little opportunity for him to acquire sufficient knowledge to become a "safe ophthalmologist." The examinations have shown that this is not the fact.

The individual who has a regular residency has definite advantages. His time is planned and the work in the basic sciences is supervised and often spread out over a sufficiently long time to make it simpler for him to acquire the knowledge. He is assigned to the laboratories where, at his leisure, he may work and study. Time is set aside during which various men in the department devote their energy in teaching him the clinical aspect of the specialty. He is taught to write and present papers. He has the advantage of working in the clinic and hospital in company with other residents. His evenings are free to study or, in some centers, to attend lectures. All in all it is an ideal and pleasant method of obtaining training.

Unfortunately, not all residencies live up to this ideal method. In some clinics the resident is used for the benefit of the organization without the organization giving its fair share in return. From the examination of candidates from such institutions it is apparent that little time has been spent in

supervision or teaching. That this supervision is necessary is very apparent. There have been some instances where the chief of the department lost interest in the teaching of residents and the candidates coming up for examination under this regime show lack of proper training.

What of the man who has been denied the privilege of a residency and who must depend upon a preceptorship for his training? The examinations have shown that it is possible to obtain an excellent training by this method. It does, however, require a longer time. In addition, there must be the "will to win" as the man must do his studying at night when he is fatigued from a hard day's work at the office. The examinations have also brought out the fact that in most instances it is necessary for the student to take a course in the basic sciences. Whether it be one of the longer courses or the very concentrated course of the Ophthalmological Study Council (The Lancaster Course) appears to make little difference.

In the preceptorship much depends upon the preceptor. If the candidate is to be properly trained the preceptor must be a sound ophthalmologist who is willing to take the necessary time to teach the clinical aspects of ophthalmology. One of the candidates, who received his training from a short basic-science course and a preceptorship and who was given one of the highest average grades, was asked regarding his training. His preceptor, in one of the small communities in Texas, spent a certain amount of time each evening after office hours discussing the cases of the day that offered unusual problems, thus allowing the student the opportunity to acquire clinical knowledge and judgment.

Thus the examinations have brought out the fact that, while a carefully supervised residency is the ideal method of obtaining a training in ophthalmology, it can be obtained from a combination of a basic-science course and a preceptorship. The examinations have also shown that a man may go through a

poorly supervised training to make him a safe ophthalmologist. It therefore becomes evident that those in charge of the training of younger men in ophthalmology, whether in a residency or a preceptorship, assume a grave responsibility in making certain that these men receive the necessary personal supervision and instruction.

Frederick C. Cordes.

GOETHE AND COLOR

During his life, and even more since, Johann Wolfgang von Goethe has excited homage and adulation. His family home has been quickly rebuilt after the war's destruction. The mineral, goethite (hydroxide of iron), was named in his honor. The bicentennial of his birth, August 28, 1749, received world-wide attention. A universal man of genius, like Leonardo da Vinci and Benjamin Franklin, Goethe was a writer, poet, statesman, theatre director, and naturalist.

Before completing his law course at Strasbourg, in 1770, Goethe had a serious pulmonary hemorrhage and, during his lengthy convalescence, pored over books on occult philosophy, alchemy, astrology, and religious mysticism. Converted finally to the philosophy of Spinoza, he henceforth considered individual creeds and dogmas unnecessary.

While in his student boarding house, he was impressed by the enthusiasm of the students of medicine. . . . "These, as is well known, are the only students who discuss with energy out of school hours their science and profession." He visited the clinics, watched Schilling in his expert cataract surgery, and observed attentively as Lobstein performed a type of dacryocystorhinostomy on his companion, Herder. Goethe felt strongly that "The physician must be creative if he is really going to heal. If he is not creative then he . . . will be a mere bungler at his work."

Goethe's literary productions from 1771 to 1775 gave him renown and influential friends. In 1775, he was appointed state councilor at the Saxon capital of Weimar, and his concern with the productive capacity of the duchy restimulated his interest in the natural sciences. His scientific thinking was speculative, poetic, and intuitive rather than empirical, analytical, and critical. Everywhere Goethe sought for and found continuity. "The plant goes from knot to knot, closing at last with the flower and the seed. So the tapeworm, the caterpillar, goes from knot to knot and closes with the head. Man and the higher animals are built up through the vertebrae, the powers being concentrated in the head." Goethe had the view that all variations in plants and animals were only metamorphoses of a primitive archetype, and not evolved one from the other, as Darwin later enunciated.

Being an amateur artist, Goethe studied pictorial art in 1768 and from this stemmed his interest in anatomy and color. Peering through a prism at the broad luminous surface of a sheet of paper on a dark background, he noted that he saw the colors only where the white paper and the dark background had a common boundary. He immediately concluded that Newton's theory is false, and that every color was merely the mixture of light and darkness in new proportions. The prism only served to move light and darkness over each other. He rejected the "artificial" theory of seven colors —the fundamental colors were just black and white. Color was solely a problem of sensory perception and he abhorred the intrusion of mathematics and physics into the subject. "Nature refuses to be unveiled by force. What she does not reveal to your mental sight you will not wrest from her with levers and screws." He refused to admit that yellow is red-green, that white is red-green-blue, and that black is a negative sensation.

He first advanced his theories in 1791 and would not be dissuaded by criticism from the completion of his monumental work, *Zur Farbenlehre*, in 1810—a two-volume

octavo of 1,510 pages and 16 colored plates. The observations recorded are astonishingly numerous and varied, from which artists have derived great benefit, as exemplified, to note only one instance, by their frequent discriminating use of colored shadows. Of this opus, Goethe wrote: "As for what I have done as a poet I take no pride whatever . . . but in my century I am the only person who knows the truth in the difficult science of colors—of that I say I am not a little proud." Two English translations have appeared, the first by Charles Locke Eastlake, the second by John Tyndall.

Though disdained by scientists, the monograph created a great sensation, and Goethe's views were widely accepted by philosophical writers, such as Hegel and Emerson. Herman Grimm declared, "Considered as a book . . . the *Theory of Colors* is truly enchanting." Lord Brougham, in his formal review, called the work a case of hallucination. The French Academy, at the advice of Cuvier, refused to consider it seriously. Helmholtz has labelled it as "the extravagancies of a great genius wandering out of his sphere."

Purkinje's dissertation on subjective visual phenomena, in 1819, won for him the friendship of Goethe, and partly through Goethe's influence Purkinje was appointed professor of physiology at the University of Breslau in 1823. Goethe's work inspired a psychologic school in which sensation rather than physical stimuli were stressed, with Purkinje, Brücke, Aubert, and Hering as typical representatives. The psychologic difficulties of accepting a purely physical interpretation of color have inspired several theorists to compromise hypotheses, such as those of Fick, Hering, and Ladd-Franklin.

On the night of his death, March 22, 1832, Goethe's last distinct words were "Mehr Licht! Noch mehr Licht!" and his keen eyes then closed forever.

James E. Lebensohn.

CORRESPONDENCE

ELECTROCOAGULATION OF THE SCLERA

Editor,
American Journal of Ophthalmology:

I have read with interest the article in your June number by Dr. Harold G. Scheie and Dr. Bourne Jerome on this subject, and agree with the conclusion they draw that electrocoagulation causes shrinkage of the eye. This fact will be known to all surgeons who have operated on a detached retina and who have found that the cornea becomes hazy from raised intraocular pressure after several diathermy applications. This corneal haze caused by scleral shrinkage and raised pressure is relieved immediately if a scleral perforation is made.

The point of this letter, therefore, is to question the conclusions of your authors that shrinkage of the globe by this means might be employed as an alternative to scleral resection in the treatment of some detachments.

Electrocoagulation causes a severe intraocular reaction and for that reason can only be applied to the eye with safety in very limited amounts. To carry out this treatment over half the circumference of the globe and so produce sufficient shrinkage is an unwise procedure causing too much damage to the eye, and it is for this reason that scleral resection, which causes no severe intraocular reaction at all, is used in those severe detachments too extensive for diathermy to replace.

It will be known to those surgeons who have carried out scleral resection that the intraocular reaction is less than that of an ordinary diathermy operation.

I, therefore, give the opinion that while there is no doubt that electrocoagulation causes shrinkage of the sclera, this same method cannot replace surgical removal of a strip of sclera where this treatment is indicated.

(Signed) Seymour Philps,
London, England.

Dr. Scheie's reply

Editor,
American Journal of Ophthalmology:

The communication received from Mr. Philps serves to emphasize points brought out in our paper "Electrocoagulation of the sclera: Reduction in ocular volume and pathologic changes produced," AMERICAN JOURNAL OF OPHTHALMOLOGY, volume 32, part II, June, 1949, pages 60-78.

We demonstrated rather marked changes in the animal eyes used in our experiments with surface electrocoagulation. Engorgement of the retinal vessels, particularly in the nerve-fiber layers, associated with hemorrhagic phenomena was striking. The final retinal atrophy was considerable.

We concluded by stating, "although surface diathermy produced a high degree of scleral shrinkage, the associated pathologic changes were of such a severe nature that clinical application to this same extent would probably be inadvisable." Further work is now in progress on the problem.

(Signed) Harold G. Scheie,
Philadelphia, Pennsylvania.

Pterygium surgery

Editor,
American Journal of Ophthalmology:

In your issue of July, 1949, Dr. H. Saul Sugar paid me a graceful compliment by saying that it was the stimulus of my paper in the *British Journal of Ophthalmology* in February, 1948, that led to the writing of his paper on the "Surgical treatment of pterygium."

In return I would like to congratulate Dr. Sugar on his own well-conceived operation; I will pay him the practical compliment of performing his operation in Australia.

It would appear that Dr. Sugar is substantially in agreement with me, with the addition of certain very sound amplifications of his own, as to the essential nature of pterygium.

He feels, however, that my procedure of removing the whole of the subconjunctival tissue from the cornea to the plica semilunaris is fraught with danger to the internal rectus muscle.

Here I must beg to differ from my distinguished colleague for two reasons:

Firstly, as the subconjunctival tissue is dissected away from the uplifted conjunctival mucosa, held up vertically with fixation forceps by an assistant, interference with the underlying muscle cannot very well occur.

Secondly, over a period of some 10 years, no interference with the action of the internal rectus muscle has been noted, either by myself or by such of my Australian colleagues who use my technique.

In conclusion, however, this stimulating thought remains with me: how pleasant it is that an American surgeon, presenting his own excellent views on a subject, should give generous credit to a paper by an Australian, printed in a British journal.

(Signed) Arthur D'Ombrain,
Sydney, Australia.

First human electroretinogram

Editor,
American Journal of Ophthalmology:

As a footnote to the centennial perspective on "Electrophysiology," editorially noted by Dr. James E. Lebensohn in the August, 1949, issue of the JOURNAL, it may interest your readers that an account of the first human electroretinogram was published by R. H. Kahn and myself (Arch. f. Ophth., 114:304, 1924). In Karpe's recent monograph on human electroretinography (1948), this priority is acknowledged. With grief I must add that my dear friend, R. H. Kahn, perished in Prague during the war.

(Signed) Arnold Loewenstein,
Glasgow, Scotland.

ELECTRICAL CONTROL FOR ASTIGMATIC CROSS

Editor,

American Journal of Ophthalmology:

In the September, 1949, issue of the JOURNAL, Dr. Horace L. Weston has an interesting account of an electrical method for revolving his astigmatic cross. Since I set up an arrangement similar to his four years ago, some suggestions may be of interest to others thinking of building such a remote control system.

One transmitter (control unit) may be made to drive an additional receiver—thus an astigmatic dial may be mounted in front of a pointer, the latter being rotated so as to indicate the most prominent line on the dial. As this receiver is driven in synchronization with the one turning the pointer, further setting of the pointer is minimized.

There is no need to use mechanisms which hum and require transformers for the surplus market is still glutted with fine units operating silently on 115-volts, 60-cycle A. C. These units are known as servo mechanisms. The two types are called transmitter and receiver. General Electric calls its units Selsyns (self synchronizing motors).

If the pointer and cross are not made extremely light, annoying chatter or oscillation will occur.

Petaluma, California.

BOOK REVIEWS

OCULAR SIGNS IN SLIT-LAMP MICROSCOPY. By James Hamilton Doggart. St. Louis, C. V. Mosby Company, 1949. 98 pages, cloth binding, 93 illustrations, 85 in color; bibliography, index. Price, $6.75.

In recent years there has been no small adequate textbook on slitlamp microscopy that has been available to the resident or student in ophthalmology. The text by Berliner is too ponderous and expensive. The monumental volumes written by Vogt are so difficult to obtain that they are not available for the student. The German language difficulty of the first two volumes is an additional handicap.

Thus Doggart's book fills a long-felt need, as a textbook for practical slitlamp microscopy for the postgraduate student.

As the author states in the preface, "bearing in mind the requirements of postgraduate students, the present writer has relegated the history of slitlamp microscopy to a short final chapter, and mathematical optics he has altogether eschewed. The apparatus is described in an appendix, and in order to forestall the criticism that this is the wrong approach, I would emphasize that such descriptions are seldom of interest, save to those who already know something about the apparatus. Therefore it is intended to plunge immediately into the clinical aspects of slitlamp microscopy with the object of helping the beginner."

The book is divided into nine chapters which discuss the value of the slitlamp technique of examination, the normal eye, corneal abnormality, aqueous disturbances, pathologic signs in the iris, lenticular changes, changes in the vitreous, and the evolution of slitlamp microscopy of the living eye.

On the whole the text is excellent. The chapter on the technique of examination is clear and concise and will be very helpful to the beginner in learning to use the instrument. The author's advice that slitlamp microscopy of the living eye should always be preceded by "naked-eye inspection" and by examination with the simpler methods is a factor that is all too often overlooked by the present-day student of ophthalmology. In discussing the pathologic changes a little more detail would seem to have been worthwhile.

In any textbook on slitlamp microscopy, colored illustrations are important. Of the 93 illustrations the book contains, 85 are in color. Some of the illustrations have been used in other books and publications of the author. Most of the pictures, however, are published in this volume for the first time. The original drawings are excellent and are

very well reproduced. They add a great deal to the value of the book.

The bibliography is comprehensive and is a good source of references for anyone interested in doing further work in some phase of slitlamp microscopy. Those books or journals giving further references to the literature are marked.

The index is complete and is an additional valuable factor in the book. The format and binding are excellent.

The book is a must for every student of ophthalmology.

<div align="right">Frederick C. Cordes.</div>

Revista de Oftalmologie. July-September, 1948, volume 1, pp. 1-204.

In this first volume of Rumania's new journal of ophthalmology, Bailliart publishes his reflections on the theories of vision, a subject for which he suggests a program of ophthalmic investigation. He also emphasizes the importance of a clear understanding of the specific photochemical and electrical reactions in the retina for other fields of science such as television which uses a mechanism similar to that of the retina.

Little is known of the details of the chemical composition or action of rhodopsin and its allied substances, of the functions of the rods and cones, the intercommunicating fibers of the different retinal layers, of the relative differences in the perceptive powers of the nasal and temporal retina, of the details of color vision, and of the shadow formation on the neuro-epithelium of the retinal vessels.

G. Bietti considers the etiology of trachoma and the effects of the sulfonamides and anitibiotics on this disease. The elementary and initial bodies cannot be considered to be Rickettsia because they are affected by the sulfonamides but are resistant to para-amino-benzoic acid which is specific for the Rickettsia. They cannot be interpreted as degenerated and phagocytized bacteria because they react to the sulfonamides and pencillin but not to streptomycin,

in spite of the equal antibacterial effect of these substances. They are not degenerative reactions of the cells but are vital elements. All studies seem to suggest that the elementary and initial bodies are the corpuscular form of the trachoma virus.

A. Bussacca's article on pericorneal and corneal vascularization in keratitis is a chapter from his monograph on the pathology of the eye. He discusses the limbal network, superficial and deep vascularization, the exact localization and variation of corneal vessels and their involution. The paper is accompanied by several very good photographs and schematic figures.

In the longest paper of this volume, N. Blatt and M. Athanasiv report their study of the optic canal, a detailed and painstaking work in which they hoped to clarify the relation of the optic canal to diseases of the optic nerve. This paper contains a survey of the literature, a report on 10,000 adult and infant skulls, numerous tables, figures, X-ray pictures, and drawings. It discusses every possible variation in the appearance of the optic canal as found in 124 adults and 12 infants.

A. Franceschetti and C. Balavoine describe their method of keratoplasty. They use round corneal flaps, removed, if possible, within one hour after death and preserved in Ringer's solution on a specially constructed glass disc.

A. Kettesy proposes to standardize the examination of visual acuity. V. J. Munteanu describes three cases of dacryocystitis treated with pencillin. D. Lazarescu and P. Toporas discuss the physiologic variations of intraocular pressure. V. Sabadeanu and C. Henter contribute a paper on epidemic keratoconjunctivitis. N. Zolog stresses the allergic factor in phlyctenular keratoconjunctivitis and reports his experience with 25 patients treated with a hormone of the reticuloendothelial system which appears in large amounts in the blood of animals blocked by electronegative colloidal solutions.

ABSTRACT DEPARTMENT

Abstracts are classified under the divisions listed below. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. Anatomy, embryology, and comparative ophthalmology
2. General pathology, bacteriology, immunology
3. Vegetative physiology, biochemistry, pharmacology, toxicology
4. Physiologic optics, refraction, color vision
5. Diagnosis and therapy
6. Ocular motility
7. Conjunctiva, cornea, sclera
8. Uvea, sympathetic disease, aqueous
9. Glaucoma and ocular tension
10. Crystalline lens
11. Retina and vitreous
12. Optic nerve and chiasm
13. Neuro-ophthalmology
14. Eyeball, orbit, sinuses
15. Eyelids, lacrimal apparatus
16. Tumors
17. Injuries
18. Systemic disease and parasites
19. Congenital deformities, heredity
20. Hygiene, sociology, education, and history

11
RETINA AND VITREOUS

Santoni, A. Seasonal variations and frequency of retinal detachments. Giorn. ital. oftal. 1:418-424, Sept.-Oct., 1948.

A statistical analysis of 610 cases of retinal detachment studied in the period from 1936 to 1947, showed a peak of incidence during the months of June and July, slightly less during May and August, and least in December. The possible significance of this finding is discussed.

Vito La Rocca.

Sautter, Hans. Experimental spasm and the effect of vasodilators on retinal vessels. Klin. Monatsbl. f. Augenh. 114:333-346, 1949.

Visible contraction of retinal arteries can be brought about by intravenous injection of adrenaline. The dose necessary for this effect usually kills the animal. Injection into the vitreous leads at once to an ever increasing interruption of the retinal circulation. The vascular constriction is followed by a dilatation with secondary diapedesis of blood through the damaged capillary walls. The milky opacity during the constrictory phase is a pure ischemia. Intercellular edema is manifest during the phase of dilation as pseudocircinate retinitis caused by capillary damage. Hemorrhages and intercellular edema occur only during incomplete interruption of the flow of blood, never in complete embolism. Late effects of intravitreal injection of adrenaline into rabbits' eyes were degenerative changes in the choroid and pigmentary disturbances in the retinal periphery similar to retinitis pigmentosa. Vasodilators like acetylcholine and similarily acting agents were usually incapable of relieving the arterial spasm or the edema, even when injected into the vitreous. They were even less effective or seemed to increase the constriction if given in combination with atropine. The desirability of a new agent which dilates the vessels, but does not lower the blood pressure is stressed for the treatment of thrombosis and embolism. (8 figures, references.)

Max Hirschfelder.

Scheerer, R. Retinal diseases from the viewpoint of the constitution theory of Kretschmer. Klin. Monatsbl. f. Augenh. 114:319-328, 1949.

The two basic types in Kretschmer's theory of constitution are the leptosome type and the pycnic type. The fundus of leptosomes usually shows thin arteries, a physiologic ischemia, a thin retina and a sclerotic choroid. The pycnic type shows a "moist" retina with broad vessels, and slight transparency and tends to approach the picture of a hypertonic fundus. Influence of general constitution is noted in several ocular diseases. Venous thrombosis is more frequent in the pycnic type with arteriosclerosis and other circular disturbances. Albuminuric retinopathy is more frequent in pycnic types, while chronic nephritis occurs in leptosomes. In glaucoma simplex one finds more leptosomes and in only 14 percent of them was vasoneurosis or arterial hypertension found. On the other hand, 67 percent of the patients with acute glaucoma, most of them of the pycnic type, had this finding. Life expectancy with acute glaucoma seems to be ten years less than with chronic simple glaucoma. Senile macular degeneration, found in "dry" retinas of chronic nephritis, occurs in leptosomes, whereas disciform degeneration of Kuhnt-Junius belongs to the "moist" retina of general vascular hypertension. (7 figures, references.)

Max Hirschfelder.

Scuderi, Giuseppe. **Macular retinitis of brown color.** Rassegna ital. d'ottal. 18:82-96, March-April, 1949.

In 1946 Dejean and Laporte described a peculiar form of tuberculous retinitis of the macula and perimacular region. Its four stages are 1. a reddish-yellow alteration of the macular area of round or oval form, 2. the color changes to brick-red and the disc becomes hyperemic, 3. grayish nodules appear around the macula, 4. after several years black pigment spots are seen in a ring around, and in the macula. Scuderi's patient was a youth, 17 years of age, whose father had died of tuberculosis. Evidences of pulmonary changes were noted in the patient. The right eye only was affected. The article is illustrated with 8 figures, 4 in color, and 2 diagrams made by autoendoscopy by the patient. Eugene M. Blake.

Stown, M. N. **Hyperplasia of the pigment epithelium of the retina simulating a neoplasm.** Tr. Am. Acad. Ophth. pp. 674-677, July-Aug., 1949.

The ocular condition in the left eye of a white man, aged 49 years, had been clinically diagnosed as von Hippel's disease ten years ago. Now sections showed marked proliferation of the pigment epithelium in a mass over the optic nerve head where bone changes also occurred. Some sections resembled neoplasm because of the marked proliferation of retinal epithelium. Lymphocytes, plasma cells and plasmacytoid cells diffusely infiltrated the anterior choroid. The retina was detached. Chas. A. Bahn.

Verzella, Mario. **A new therapy for retinitis pigmentosa. Juxtabulbar injections of nicotinic acid.** Giorn. ital. oftal. 1:331-358, July-Aug., 1948.

The author explains the characteristics of a new therapeutic technic based on intense hemo-dynamic action by massive local injections of nicotinic acid on the eye. After describing the technical modifications of injections, and trying to clarify the mechanism of action, the author reports concisely the history of 12 patients and the results obtained. He comments briefly on the favorable functional changes. Vito La Rocca.

12
OPTIC NERVE AND CHIASM

Bedell, A. J. **Perineuritis optica.** Tr. Am. Ophth. Soc. 46:399-411, 1948.

Four cases in which unusual signs

temporarily confused the diagnosis are reported and illustrated with serial fundus photographs. Serial fundus photography was also valuable in establishing the diagnosis in an unusual senile macular degeneration in a myope with hyperpiesia, a rare form of optic neuritis with a sharply localized edema of part of the nerve head in multiple sclerosis, syphilitic neuroretinitis simulating occlusion of the central retinal vein and traumatic retinal angiopathy, and tuberculous retinitis with severe optic nerve reaction and complete resolution of the focus with restoration of function.   David O. Harrington.

Blatt, N. **The value of malarial therapy in syphilitic optic atrophy.** Ann. d'ocul. 182:513-520, July, 1949.

The results of treatment in 387 cases of syphilitic optic atrophy during 20 years are analyzed. It can be easily seen that the prognosis of syphilitic optic atrophy is much worse in those treated with malarial therapy than in those treated by other methods or even untreated.
                            Chas A. Bahn.

Dresner, E., and Montgomery, D. A. D. **Primary optic atrophy in von Recklinghausen's disease (multiple neurofibromatosis).** Quart. J. Med. 18:93-104, April, 1949.

The authors described three cases of optic atrophy in which multiple neurofibromatosis was the cause. Two of them occurred in uniovular twins. The third patient came to autopsy and an astrocytic glioma of the optic nerve was found. Primary optic atrophy has been found with von Recklinghausen's disease in 46 instances. In 41 cases in which histologic studies of the optic nerve were made there were 35 primary gliomas of the nerve or chiasm.   R. Grunfeld.

Friemann, W. **Hereditary optic atrophy**

in women. Arch. f. Ophth. 149:266-274, 1949.

A pedigree is presented with familial optic atrophy in women of two generations. In Leber's optic atrophy men are usually affected.   Ernst Schmerl.

Paufique, L., and Etienne, R. **Depressed colobomata of the papilla.** Ann. d'ocul. 182:605-615, Aug., 1949.

This unusual developmental anomaly is usually unilateral and seldom multiple. The color of the depression is usually gray, involves $\frac{1}{8}$ to $\frac{1}{3}$ of the temporal part of the papilla, and its depth varies from 1 to 6 mm. Pulsation from the central retinal vessels may be observed. Vision is variably affected and central and paracentral scotomata may be present. In some cases a hereditary factor has been established, and other ocular degenerations such as macular cysts, congenital cataracts and microphthalmus may be coexistent. This anomaly is caused by an imperfect invagination of the primary optic cup. Two cases are described.
                            Chas. A. Bahn.

13
NEURO-OPHTHALMOLOGY

Capolongo, Giuseppe. **Chronaximetry in ophthalmology.** Riv. oto-neuro-oftal. 23:371-386, Sept.-Dec., 1948.

The phosphene from an electric stimulus occurs at the level of the occipital cortex where the retina and the optic nerve are not intact and its chronaxy cannot be considered indicative of the functional state of the retina and the optic nerve.   Melchiore Lombardo.

Cibis, P., and Lazar, O. **Disturbances of the lower visual functions in injuries of the brain.** Klin. Monatsbl. f. Augenh. 114:346-356, 1949.

In this statistical evaluation of 157 pa-

tients with brain injuries in World War II it was found that over one half of them had injuries to the posterior part of the skull. Of all the injured, 94 percent had better than half vision in the better eye and none was completely blind. Two of the patients had injuries of the optic tract with complete hemianopsia. The functioning half of the visual field reacted normally to adaptation tests, which is never found in injuries to the occipital lobe. About one third of the injured showed hemianopsias in the peripheral field, half of which were bilateral. A great majority showed "sparing of the macula" in the presence of peripheral hemianopic defects. The "spared area" showed damage of adaptation as well as of color distinction, which is ascribed to a change in the function of the cones in the area of central vision. (References.)

Max Hirschfelder.

Grignolo, Antonio. A case of Claude Bernard-Horner syndrome from zona ophthalmica. Riv. oto-neuro-oftal. 23:387-392, Sept.-Dec., 1948.

A man, 57 years of age, soon after an attack of herpes zoster of the first branch of the trigeminus was found to have ptosis, miosis and enophthalmos on the same side. There was a spasm of the orbicularis, hypesthesia of the cornea and sluggish reaction of the pupil to light. The pupil became dilated after instillation of atropin and adrenalin but not of cocaine. This indicates that the lesion was between the superior cervical ganglion and the pupillary dilator just where the sympathetic fibers come in contact with the Gasserian ganglion. It is probable that the Horner syndrome was in this case caused by a diffusion by contiguity of the herpetic process from the trigeminus to the ocular sympathetic fibers.

Ernst Schmerl.

Pampiglione, Giuseppe. The electroencephalographic research in intracranial tumors. Riv. oto-neuro-oftal. 23:353-370, Sept.-Dec., 1948.

Many electroencephalograms are shown to demonstrate the importance of this test in the diagnosis and the localization of the cerebral neoplasms. (12 figures, references.) Melchiore Lombardo.

Poos, F. Paradoxical adrenaline mydriasis. Ophthalmologica 118:127-136, Aug., 1949.

The term paradoxical adrenaline mydriasis is applied to the well-known phenomenon of greater efficacy of topically applied adrenaline solutions in sympathetically denervated eyes. Instillation of adrenaline hydrochloride in 0.1-percent concentration produces appreciable mydriasis in the sympathetically denervated, but not in the normal eye. According to the conventional explanation of this phenomenon the denervated effector cells are more sensitive to adrenaline than the normally innervated dilator cells. The author is opposed to this concept of sensitization of the denervated muscle and adduces new evidence which suggests a different explanation. His main point is that the pupillomotor impulses elicited by changes in the light adaptation of the retina raise the threshold concentration of any mydriatic. The true threshold concentrations should be determined on sightless but otherwise normal eyes (a state apparently produced by severing the optic nerve close to the globe). A different and considerably higher threshold con-

centration is obtained if one determines the smallest concentration of a drug that overcomes the pupillomotor impulses serving retinal adaptation. Adrenaline in 0.1-percent concentration produces marked mydriasis in blind rabbits' eyes in which the retina no longer exerts its dominating effect upon the pupil. Even in normal rabbits' eyes a mydriatic effect of instillations of 0.1-percent adrenaline can be demonstrated if the observations are made at very low degrees of illumination.

The specific case of a marked change in the size of a sympathetically denervated pupil in man after the instillation of 0.1-percent adrenaline which produces no measurable change in the opposite, normal, eye may be explained as a result of the existing anisocoria. The width of the normal pupil is chiefly governed by retinal influences. A weak mydriatic would have to overcome these retinal influences in order to dilate the pupil. In the denervated, relatively miotic eye the weak mydriatic can produce a measurable dilation of the pupil without having to overcome the retinal pupillomotor factor and, moreover, the absorption of drugs from the conjunctival sac, the author believes, is better on the denervated than on the normal side. Peter C. Kronfeld.

Weekers, R., and Roussel, F. The mode of action of retrobulbar injections of alcohol. Ophthalmologica 118:115-126, Aug. 1949.

The authors review the anatomy, physiology and pharmacology of the sympathetic and parasympathetic innervation of the anterior uvea. In order to elucidate the mode of action of retrobulbar alcohol injections in man, the authors have performed such injections in rabbits. The effects of these injections have been very uniform and consisted of mydriasis, dim-inution or abolition of the light reflex of the pupil, hypersensitivity to topical application of mecholyl and insensitivity to eserine. In most cases these effects have been transient and followed by complete recovery. The retrobulbar injection apparently produces a postganglionic, predominantly parasympathetic, reparable lesion. The sympathetic fibers escape injury because of their more dispersed course within the orbit. After retrobulbar alcohol injections in man, lasting pupillary disturbances are very rare. The authors report four such cases with pupillary reactions closely resembling those of Adie's syndrome. Some, but not all cases of Adie's syndrome are due to postganglionic parasympathetic lesions.

Peter C. Kronfeld.

EYEBALL, ORBIT, SINUSES

Heimburger, R. F., Oberhill, H. R., McGarry, H. I., and Bucy, P. C. Intraorbital aneurysm; a case of aneurysm of the lacrimal artery. Arch. Ophth. 42:1-13, July, 1949.

A case of exophthalmos due to aneurysm of the lacrimal artery contained entirely within the orbit is reported. The lesion was removed by the transcranial route, and the patient is entirely well, over a year after operation, with normal vision and normal ocular movements. A survey of the literature revealed no other verified case of aneurysm of the lacrimal artery. Reports of six intraorbital aneurysms seen either at operation or at autopsy are reviewed, but in none is the diagnosis without question. The case presented is evidence that orbital aneurysm can be manifest clinically by unilateral exophthalmos without pulsation, but with evidence of venous obstruction, increased ocular tension and failing vision.

Ralph W. Danielson.

15
EYELIDS, LACRIMAL APPARATUS

D'Ermo, F. Further contribution to the surgical treatment of the jaw winking phenomenon. Boll. d'ocul. 28:207-215, April, 1949.

After discussing previous approaches to this problem, D'Ermo describes two patients, aged 22 and 23 years, who were satisfactorily operated on according to the method of G. Bietti. His method is a combination of the technics advocated by Hess and by Angelucci. It was published by Bietti in the Boll. d'ocul. 21: 721, 1942. A large skin pocket is prepared by undermining the skin of the lid and separating it from the orbicularis muscle, beginning at the eyebrow and ending above the lid border. Separating the orbicularis fibers gives access to the levator muscle which is isolated and cut one half centimeter from its tarsal insertion. The distal muscle end is secured by three catgut sutures which are led through the frontalis muscle three centimeters above the eyebrow. Here, two more catgut sutures may be added on both sides of the original three sutures in order to strengthen the hold of the muscle stump in its new position. Two double-armed silk sutures are passed through the lid skin 4 millimeters from the lid border, from the outside towards the pocket, and led through the frontalis muscle to come to the surface 3 to 4 centimeters above the eyebrow. When the sutures are knotted, the two lower thirds of the cornea must remain uncovered by the upper lid. Regulation of the pull during the early postoperative period is indicated. The silk sutures are removed after 8 to 10 days. In both cases, the cosmetic result was satisfactory and the synkinetic movements with opening of the mouth, chewing, and lateral movement of the jaw were abolished. (12 figures, references.)

K. W. Ascher.

Nuti, F. Etiologic explanation of a case of mycotic dacryocanaliculitis (Conistreptothrix Försteri). Boll. d'ocul. 28:169-178, March, 1949.

A 33-year-old woman developed purulent discharge from both canaliculi of her right eye one year after dacryocystectomy was performed. The opened canaliculi yielded numerous grayish-yellowish concrements some of which were inoculated into the anterior chamber of a rabbit, the remainder cultivated on aerobic and anaerobic media. In the rabbit eye the germ provoked a mild inflammatory process of the posterior corneal layers. The cultures proved the presence of a Conistreptothrix, most probably Försteri. Nuti raises the question whether some similar case previously attributed to actinomyces might have been caused by the same Conistreptothrix. K. W. Ascher.

16
TUMORS

Negri, L., and Alajamo, A. Tumors of the uveal tract and their cytogenesis. Giorn. ital. oftal. 1:289-316, July-Aug., 1948.

In a histologic study of 24 tumors of the choroid and one of the ciliary body stained with hematoxilin-eosin and a trichromic stain to show the reticulum, it was found that the pigmentation of the tumors is not enough for differential diagnosis on the basis of cellular morphology. They agree with Callender and Wilder that abundance in silver-staining fibers indicates less malignancy. The hypothesis of the origin of these tumors from a proliferation of the cells of the sheath of Schwann of the ciliary nerves deserves consideration, but requires further study.

Vito La Rocca.

Wolff, E. The nature of the malignant choroidal melanomata. Brit. J. Ophth. 33: 445-452, July, 1949.

To support the theory that malignant choroidal melanoma is a sarcoma and that it is derived from the cells of Schwann of the ciliary nerves, Wolff points out that melanoma, like sarcoma, does not produce a local tissue reaction as does carcinoma. Blood vessels in sarcoma and melanoma are like new-formed vessels in that they have no walls of their own but are surrounded by tumor tissue. Teased tissue preparations show that the chromatophore and not the epithelioid cell is the essential cell of the melanoma. (6 figures.)

Morris Kaplan.

17
INJURIES

Ghose, Nirmal Kumar. Unusual ocular foreign body. Brit. J. Ophth. 33:520-521, Aug., 1949.

The author describes an unusual irritating foreign body, a small snail that was removed after it emerged from under the conjunctiva. This organism easily survives in the sheltered subconjunctival tissue but rapidly dies upon exposure to air.   Orwyn H. Ellis.

Schreck, E. Gas gangrene and the eye. Klin. Monatsbl. f. Augenh. 114:364-370, 1949.

The clinical, bacteriologic and histologic data on a patient who developed an intraocular infection with gas bacillus after perforation with a piece of metal are reported. Early panophthalmitis with rapid amaurosis and ocular hypertension and necrosis of the wound margins aid in the clinical diagnosis. Gas formation can sometimes be observed with the slit lamp or during operation. Gangrene of the ocular tissues with edema and necrosis as well as hemolysis and formation of methemoglobin were the pathologic characteristics. The patient received gas gangrene serum, sulfonamides and penicillin and recovered uneventfully after the

enucleation of the bulbus. (3 figures, references.)   Max Hirschfelder.

18
SYSTEMIC DISEASE AND PARASITES

Ashton, N. Vascular changes in diabetes with particular reference to the retinal vessels. Brit. J. Ophth. 33:407-420, July, 1949.

Histologic studies of vessel changes throughout the bodies of 21 diabetics were made and minutely compared. Tissues examined included those of the retina, choroid, ciliary body, iris, conjunctiva, brain, meninges, pleura, pericardium, omentum, peritoneum, bladder mucosa and the capsules of the kidney and liver. The details of fixing and staining all tissues are described. The suggestion that the lesions in the retina are micro-aneurysms is confirmed and it is shown that these dilatations occur in no other tissue. They occur mainly in the inner nuclear layer and are possibly caused at least partly by a venous stasis in this area brought about by fluctuations in ocular tension although this explanation is unsatisfactory and more work remains to be done. The retinopathy and the intercapillary glomerulosclerosis are very closely related etiologically and result from the same pathologic process whose manifestations differ in the eye and the kidney because of the different anatomic pattern of the retinal and glomerular vessels. (25 photographs.)

Morris Kaplan.

Botasso, Giovanni. Posthemorrhagic amaurosis. Rassegna ital. d'ottal. 18:121-129, March-April, 1949.

Loss of sight from hemorrhage occurs most often from gastrointestinal and uterine hemorrhage, repeated blood-letting, epistaxis and hemoptysis, in the order mentioned. In only 12 to 15 percent of cases is the ocular involvement uni-

lateral and women are oftener affected than men. The author reports an instance of bilateral blindness occurring in a 45-year-old woman after a severe metrorrhagia. Eugene M. Blake.

Di Ferdinando, R. A. **A case of palpebral leishmaniasis.** Giorn. ital. oftal. 1:359-364, July-Aug., 1948.

The author describes a case of palpebral leishmaniasis observed in a baby, 2 years of age, in the province of Pesaro-Urbino, where such disease occurs epidemically. He confirms the rarity of this dermatosis in comparison to its frequent appearance in other exposed parts of the body, which may be ascribed to local conditions of defense that hinder the action of the transmitting agent. Vito La Rocca.

Hartmann, Edward. **Psychosomatic phenomena in ophthalmology.** Brit. J. Ophth. 33:461-476, Aug., 1949.

The author presents numerous case reports to illustrate psychosomatic problems in ophthalmology. Various responses such as esotropia in children and glaucoma in adults are produced. Functional disturbances are often associated with organic conditions and it is often important that the psychosomatic disturbance be alleviated before the organic condition will respond to treatment. (42 references.) Orwyn H. Ellis.

vom Hofe, K. **Participation of general factors in inflammations of the uvea and cornea.** Arch. f. Ophth. 149:220-229, 1949.

Among the general diseases most often found in uveitis are rheumatism, tonsillitis, furunculosis, pneumonitis, otitis media and appendicitis.
Ernst Schmerl.

Ridley, A. **Toxoplasmosis, a summary of the disease with report of a case.** Brit. J. Ophth. 33:397-407, July, 1949.

Prenatal infection of the eyes of human infants by the protozoon toxoplasma is being recognized and reported with increased frequency in all countries, and here the third case to be reported in England is presented. First discovered in 1908, the toxoplasma is an intracellular parasite whose presence is easily demonstrated in post-mortem material of most of the tissues and in vivo in the spinal fluid. In man, the severity of the disease and its predilection for the eye seem to vary inversely with the age of the patient. The eye manifestions include searching nystagmus, microphthalmos, persistent pupillary membrane, strabismus, lens opacities and, most seriously, focal choroiditis which is often in both macular areas. There is usually an associated focal encephalitis with multiple areas of calcification which are demonstrable on X-ray films. A diagnostic serologic test needs refinement. Treatment is disappointing although the combination of sulphonamides and emetine is recommended. (6 illustrations.) Morris Kaplan.

19
CONGENITAL DEFORMITIES, HEREDITY

Anderson, B. **Familial central and peripapillary choroidal sclerosis associated with familial pseudoxanthoma elasticum.** Tr. Am. Ophth. Soc. 46:326-347, 1948.

A family pedigree is presented in which three of four siblings and one collateral relative have choroidal sclerosis and pseudoxanthoma elasticum. The sibling not exhibiting pseudoxanthoma elasticum presented angioid streaks and a retinal lesion resembling retinitis punctata albescens. The literature is reviewed. The hypothesis is advanced that the choroidal sclerosis is due to or associated with degeneration of the elastic membrane of the vessel wall. It is further postulated that the choroidal degeneration is due to localized anoxemia produced by the

changing pattern of the posterior ciliary arteries in the development of the orbital vascular and osseous system. The cases reported seem to substantiate the thesis that choroidal sclerosis is a clinical entity, a familial and probably a hereditary disease. Failure of the elastic tissue system may be the common denominator in angioid streaks, retinitis punctata albescens, choroidal sclerosis, pseudoxanthoma elasticum and retinitis pigmentosa.

David O. Harrington.

Azzolini, U. **The Laurence-Moon-Bardet-Biedl syndrome and similar clinical forms.** Riv. oto-neuro-oftal. 23:309-340, Sept.-Dec., 1948.

The author differentiates a chronic arachno-diencephalic form of this syndrome which he ascribes to an inflammatory meningeal process in a tissue predisposed by heredity, whereas the usual manifestation is purely heredodegenerative. A clinical case is reported for illustration.   Melchiore Lombardo.

Burns, R. A. **Hereditary myopia in identical twins.** Brit. J. Ophth. 33:491-494, Aug., 1949.

The detailed case studies and family pedigree of hereditary myopia in identical twins is reported. The twins were identical in all characteristics except for a difference in the refraction. The right eyes were almost alike but not the left. The family pedigree showed a dominant type of transmission which, however, did not appear in a later generation.

Orwyn H. Ellis.

Hepner, W. R., Krause, A. C., and Davis, M. E. **Retrolental fibroplasia and light.** Pediatrics 3:824-828, June, 1949.

The effect of light as a causative factor of retrolental fibroplasia in premature infants was studied. The authors conclude that light is not a cause of this condition.

Donald T. Hughson.

Stadlin, W. **Chorioretinal changes in two sisters with Freidrichs' heredoataxia.** Ann. d'ocul. 182:489-508, July, 1949.

This rare manifestation of this unusual disease is illustrated by two sisters whose parents were first cousins. The genealogy is traced through six generations of which they were in the fourth. The older sister was born in 1900 and the younger in 1903. Both were in good health until approximately the age of 15 years, when weakness developed in the lower extremities after an acute infection. Ataxia, scoliosis, loss of some reflexes, and ocular abnormalities slowly followed. Nystagmus was observed in both sisters about 1924. Now vision in the older sister is .1 in each eye and in the younger, .6 in each eye. The macular regions are irregularly pigmented and more so in the older. In the equatorial region the fundi contain 10 to 20 yellowish areas of various size and shape located in the external retina and choriocapillaris, most of which show moderate pigment migration. The discs and retinal vessels look normal, but the fields are moderately and concentrically contracted. The chorioretinal changes are slowly progressive. Their inflammatory or degenerative origin and the classification of tapeto-retinal degenerations alone or co-existent with cerebral and/or spino-cerebellar degenerations are discussed thoroughly.

Chas. A. Bahn.

Wilson, W. M. G. **Congenital blindness (pseudoglioma) occurring as a sex-linked developmental anomaly.** Canad., M. A. J. 60:580-584, June, 1949.

The author constructed the pedigree of six generations of an Indian family in which several males were born blind. All the females except one were free from the disease. The transmission of the defect thus revealed sex-linked characteristics. Eyes that came to enucleation from three males showed the presence of gross de-

velopmental anomalies. The eyes of males that were seen in early infancy proved to have pseudoglioma due to excessive congenital detachment of the retina.

R. Grunfeld.

20
HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Csapody, I. Writing and the surgeon. Szemészet 2:85-91, 1949.

Surgical skill often manifests itself in handwriting. Three types can be distinguished: the ease in the writing of born artists' hands, the more expressive writing of energetic people, and the small letters of careful people. Security associated with ease is the common feature of suitable hands. Consciously nice writing is a good training for both skill and will. Analysis of writing may be employed in judging candidates.   Gyula Lugossy.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
601 Union Trust Building, Cincinnati 2

News items should reach the editor by the 12th of the month but, to receive adequate publicity, notices of postgraduate courses, meetings, and so forth should be received by the editor at least three months before the date of occurrence.

DEATHS

Dr. John Arthur Spengler, Geneva, New York, died August 12, 1949, aged 81 years.

MISCELLANEOUS

GRADY CLAY MEMORIAL EYE CLINIC

On September 15th dedication ceremonies for the Grady Clay Memorial Eye Clinic were held at the Grady Clay Memorial Hospital, Atlanta, Georgia. The Grady Clay Memorial Eye Clinic is the result of the work of friends of the late Dr. Grady Edward Clay, professor of ophthalmology, who died July 12, 1946.

From the time of his appointment as head of the department of ophthalmology in 1939 until his death, Dr. Clay worked to develop an outstanding graduate training program in ophthalmology at Emory University.

Dr. Phinizy Calhoun, Sr., emeritus professor of ophthalmology at Emory University, delivered the dedication address and was followed by Dr. J. Mason Baird, director of the Grady Clay Memorial Clinic. The Grady Clay Memorial Eye Clinic building was accepted by Dr. R. Hugh Wood, dean of the Emory University School of Medicine and Dr. Alton V. Hallum, acting head of the department of ophthalmology.

The Grady Clay Memorial Eye Clinic is a two story, air-conditioned, brick building. It houses the out-patient clinics for the department of ophthalmology and the Montgomery Ophthalmological Laboratory, under the direction of Dr. Phinizy Calhoun, Jr. Instruction and conference rooms for graduate and undergraduate education and a library for ophthalmology, which is a part of the Emory University Medical Library, are also housed in the building.

Dr. Morgan B. Raiford, is fulltime clinical director of the clinic. Glaucoma and motility clinics have been organized.

ESTELLE DOHENY EYE LECTURE

The third Estelle Doheny Eye Lecture presented by the Estelle Doheny Eye Foundation will be given by Dr. Phillips Thygeson, at Los Angeles on January 17, 1950. Dr. Thygeson is associate professor of ophthalmology at the University of California Medical School in San Francisco. The subject of the address will be "The etiology and treatment of phlyctenular keratitis."

The lecture, an integral part of the foundation's functions, is named for Mrs. Edward Laurence Doheny, the foundation's benefactress. Dr. Alan C. Woods delivered the first annual lecture on December 17, 1947, and Dr. Cecil J. O'Brien, the second lecture on November 8, 1948.

SOCIETIES

WASHINGTON OFFICERS

New officers of the Washington, D.C., Ophthalmological Society are: President, Dr. J. Thomas Schnebly; vice-president, Dr. Thomas A. Egan; secretary-treasurer, Dr. Everett S. Caldemeyer; directors, Dr. Joseph Desoff and Dr. Jerome A. Sansoucy.

The meeting dates for the 1949-1950 season are November 7th, January 9th, March 6th, and May 1st. The March 6th meeting will be held jointly with the Baltimore Ophthalmological Society.

On November 7th, a dinner meeting was held at the Kennedy-Warren Hotel. Dr. Raynold N. Berke of Hackensack, New Jersey, spoke on "Ophthalmology in India," and films depicting the status of ophthalmology in India were shown.

AKRON OFFICERS

Recently elected officers of the Akron Academy of Ophthalmology and Otolaryngology are: President, Dr. C. R. Anderson; vice-president, Dr. Daniel Mathias; secretary-treasurer, Dr. A. L. Peter.
